The TAFI transcript encodes a gene product of 423 amino acids. The first 22 amino acids comprise a signal peptide that is absent in the circulating form of the protein. Three single nucleotide polymorphisms in the coding region of the human TAFI gene have been identified, resulting in two distinct isoforms of TAFI: a base change of C to T at base 678, resulting in a silent mutation; a base change of A to G at base 505, yielding a Thr to Ala substitution at amino acid position 147; and a base change of C to T at base 1,057, resulting in an Ile to Thr substitution at TAFI residue 325. No functional difference was observed between purified TAFIa (Ala¹⁴⁷) and TAFIa (Thr¹⁴⁷).²⁰³⁸ However, purified TAFIa (Ile³²⁵) showed greater activity and stability than TAFIa (Thr³²⁵).

The plasma concentration of TAFI antigen has been observed to vary approximately 10-fold in the human population. The origin of this variability appears to be primarily genetic.²⁰³⁹ Polymorphisms in the TAFI gene that have been shown to be strongly associated with plasma TAFI levels include a number in the 5'-flanking region,^{2029,2040} the 3'-untranslated region,²⁰⁴⁰ and the coding region.²⁰⁴¹

Biochemistry

The TAFI transcript specifies a preprotein of 423 amino acids composed of a signal peptide, an activation peptide domain, and a catalytic domain. Removal of the signal peptide yields the circulating zymogen of 401 amino acids (45 kDa); when analyzed by

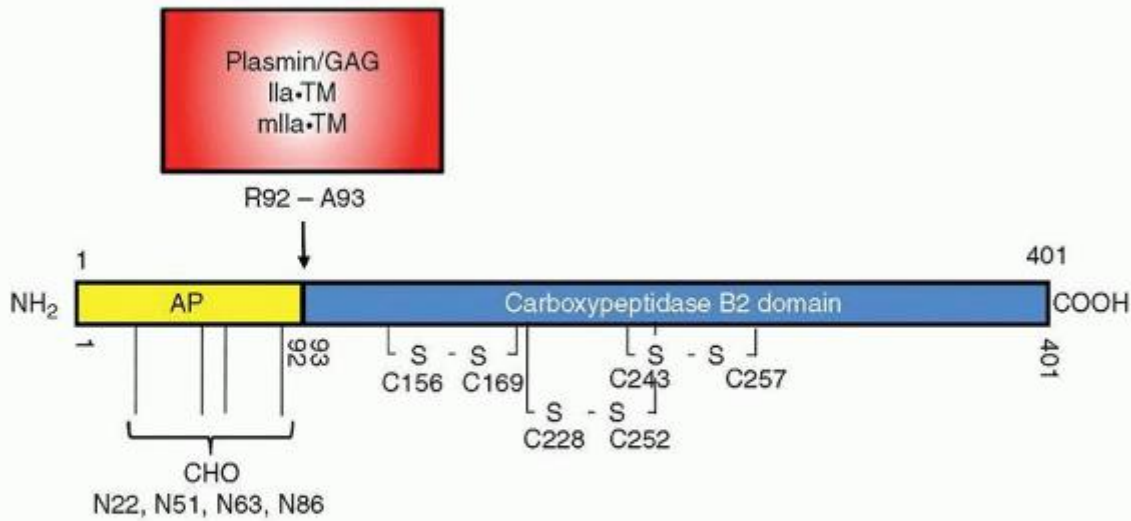

P.490

SDS-PAGE, the apparent molecular weight of TAFI is 58 kDa (Fig. 18.22). The difference in mass derives from a high level of glycosylation involving all four of the potential sites (Asn²², Asn⁵¹, Asn⁶³, and Asn⁸⁶) present in the activation peptide domain (residues 1 to 92). In addition to its structural role in suppressing the catalytic potential of TAFI, the activation peptide domain mediates the association in blood of TAFI with plasminogen.¹⁹ The sequence of the catalytic domain (residues 93 to 401; 35 kDa) displays exact conservation when compared to pancreatic and mast cell carboxypeptidases of cysteine residues and residues critical for catalysis, Zn²⁺ binding, and substrate binding.^{19,2035} The activated form of TAFI is a carboxypeptidase that catalyzes the removal of arginine or lysine residues from the COOH-termini of polypeptides. TAFIa is inhibited by agents that can chelate Zn²⁺, such as o-phenanthroline, and by 2-guanidinoethylmercaptosuccinic acid, a specific inhibitor of pancreatic and mast cell carboxypeptidases.^{19,36} TAFIa is an unstable enzyme at physiologic pH and temperature.^{18,19,36} At 37°C, TAFIa has a functional $t_{1/2}$ of approximately 10 minutes; its loss of activity is coincident with a significant change in conformation.²⁰⁴²

Activation

The activation of TAFI requires the cleavage of the zymogen at Arg⁹², yielding an activation peptide of approximately 15 kDa and an active carboxypeptidase of 35 kDa (Fig. 18.22). Trypsin,¹⁹ plasmin,^{19,2043} plasmin-anionic GAG complex,²⁰⁴³ thrombin,^{19,36} thrombin-thrombomodulin complex,⁹⁶⁹ and meizothrombin-thrombomodulin complex¹⁰⁹⁷ all catalyze this reaction in vitro. A ranking of these catalysts in terms of relative catalytic efficiency shows the following order: thrombin-thrombomodulin (1.0) > meizothrombin-thrombin (0.1) = plasmin-anionic GAG (0.1) > plasmin (0.006) > thrombin (0.0008). The complement protease MASP-1 also has been shown to activate TAFI.²⁰⁴⁴ The relative contributions of thrombin and plasmin to TAFI generation in vivo may be regulated by the availability of their respective cofactors at the site of vascular injury: cell-associated thrombomodulin versus the extent of exposure of subendothelial extracellular matrix. Platelet factor 4 has been reported to inhibit activation of TAFI by the thrombin-thrombomodulin complex.²⁰⁴⁵

FIGURE 18.22. Schematic of thrombin-activatable fibrinolysis inhibitor (TAFI). Activation of TAFI yields an exopeptidase (TAFIa) with carboxypeptidase B-like substrate specificity. It catalyzes the removal of basic amino acids (arginines, lysines) from the COOH-termini of polypeptides. TAFI contains four glycosylation sites in its activation peptide region. TAFIa is an unstable enzyme undergoing spontaneous conformational change resulting in a loss of catalytic activity ($t_{1/2} = 8-10$ min).

Function

Thrombin cleavage of fibrinogen yields insoluble fibrin polymers and soluble fibrinopeptides, all bearing COOH-terminal arginine residues. These COOH-terminal arginines are substrates for TAFIa, and the kinetics of their release in an *in vitro* clot lysis system¹⁰¹¹ and whole blood system where des-Arg FPB was detected¹⁰¹³ have been reported. The significance of this removal of arginine residues from these sites is not known. The activation of many of the cofactors and zymogens of the coagulation and fibrinolytic cascades results in the generation of functional proteins with COOH-terminal arginines or lysines. Their status as TAFIa substrates is unknown. Bradykinin and several enkephalins have been shown *in vitro* to be good TAFIa substrates²⁰³⁴; to date, only circumstantial evidence connects TAFIa and bradykinin *in vivo*.²⁰⁴⁶

Extensive *in vitro* data^{1011,1104,1775,1776,2042,2047,2048} attest to the ability of TAFIa to slow the rate of fibrin degradation by plasmin generated *in situ*. Proteolysis of insoluble fibrin by plasmin proceeds through repetitive cleavages at lysine residues terminating in the formation of soluble fibrin degradation products. Before solubilization, each cleavage shortens the fibrin molecule and generates a new COOH-terminal lysine residue. COOH-terminal lysines in partially degraded fibrin have been shown to function as potent cofactors for t-PA-catalyzed activation of Glu-plasminogen.^{2049,2050,2051,2052} and²⁰⁵³ Removal of the COOH-terminal lysines by TAFIa thus reduces the number of sites available for plasminogen binding, thereby reducing the rate of plasmin generation with consequent prolongation of fibrin dissolution^{1011,1775,2054} (Fig. 18.21). TAFIa functions as an attenuator of fibrinolysis,²⁰⁵⁵ and thus an adequate rate of TAFIa generation may be critical in the stabilization of the blood clot. For example, plasmas with specific deficiencies in the coagulation pathway showed reduced rates of thrombin production, decreased levels of TAFIa, and premature clot lysis.^{1776,2026,2056}

Regulation

TAFI circulates in plasma bound to plasminogen¹⁹ and is a substrate for factor XIIIa, which catalyzes its covalent attachment to

P.491

fibrin.¹⁰¹² Whether these two mechanisms for concentrating TAFI at the site of fibrin formation contribute to the function of TAFI in vivo is not established. It has been proposed,²⁰⁵⁷ because the thrombin-thrombomodulin complex has a K_m 10 to 20 times the plasma concentration of TAFI, that rates of TAFI activation would vary directly with changes in TAFI concentration.

A plasma inhibitor of TAFIa has not been described. Carboxypeptidase inhibitors from potato²⁰⁵⁸ and the leech²⁰⁵⁹ active against TAFIa have been identified. TAFIa is an unstable enzyme under physiologic conditions.^{18,19,36} It undergoes a spontaneous conformational change with a $t_{1/2}$ of 10 minutes at 37°C.²⁰⁴² This appears to be the primary route of inactivation because proteolytic cleavage at Arg³⁰² by thrombin or plasmin has now been identified as secondary to and dependent on the inactivating conformation change.^{2060,2061}

TAFI plasma concentrations vary significantly in the human population. Although genetic factors appear to be the largest contributor to this variation,²⁰⁴⁰ a growing number of stimuli have been shown to affect TAFI plasma concentration.^{2030,2039,2062,2063,2064} and²⁰⁶⁵ It has been proposed, in light of the intrinsic instability of TAFIa and the absence of a specific inhibitor, that control of the concentration of TAFIa through control of the level of TAFI gene expression is the primary regulator of the TAFI/TAFIa system in vivo.²⁰⁶⁶

Plasminogen Activator Inhibitor-1

PAI-1 is the primary physiologic inhibitor of plasminogen activation in blood, targeting u-PA and t-PA.²⁰⁶⁷ It also appears to have a role, independent of its antiproteolytic function, in tissue remodeling by interfering with vitronectin-dependent processes of cell adhesion and migration. Congenital deficiency of PAI-1 is rare, with homozygous individuals displaying abnormal bleeding in response to trauma.^{2068,2069,2070,2071} and²⁰⁷² In a normal population, plasma PAI-1 concentration varies over a 15-fold range (6 to 80 ng/ml; Table 18.10)^{2073,2074} and exhibits a circadian variation.²⁰⁷⁵ Some of this variability stems from polymorphisms in the PAI-1 gene; however, a larger fraction of the variability appears to derive from the responsiveness of PAI-1 gene expression to a wide variety of physiologic effectors and conditions as well as pharmacologic agents.²⁰⁷⁶ Higher levels of plasma PAI-1 prolong fibrin removal by shortening the functional lifetime of plasminogen activators, thereby shifting hemostasis to a more thrombotic state.²⁰⁷⁷ The $t_{1/2}$ of PAI-1 in blood is < 10 minutes. Potential sites of constitutive PAI-1 synthesis in humans include the liver, spleen, adipose tissue, and cells of the vasculature, including endothelial cells, smooth muscle cells, macrophages, and megakaryocytes. The relative contributions from these sources to plasma PAI-1 levels in normal or specific pathologic conditions remain unresolved. The major fraction of PAI-1 in blood is present in platelets, apparently synthesized and stored in the α -granules during the maturation of megakaryocytes.²⁰⁷⁸ Although 75% to 80% of platelet PAI-1 is present in the latent form, there appears to be enough active PAI-1 released from platelets at sites of thrombus formation to contribute to the suppression of fibrinolysis.^{1922,1923}

PAI-1 is a single-chain protein with an M_r of 50,000 (13% carbohydrate; Table 18.10). It is a typical serpin with its reactive site bond, Arg³⁴⁶-Met³⁴⁷, positioned in an exposed loop region²⁰⁷⁹ where it is available for complexation with its target proteases. However, this conformation, with the reactive site accessible to proteases, is unstable ($t_{1/2} \leq 90$ minutes), reverting spontaneously to a latent form of the inhibitor in which the reactive loop is buried in β sheet A of the protein core. This positioning of the reactive loop is observed in PAI-1 and other serpins after cleavage of the reactive site bond.²⁰⁸⁰ Plasma PAI-1 circulates in noncovalent association with vitronectin^{2073,2081} ($K_d \leq 0.05$ nmol/L); in vitro, this association results in a twofold increase in its functional $t_{1/2}$ and, in the presence of heparin, increases PAI-1 reactivity with thrombin.¹⁶⁰³

Gene Structure and Expression

PAI-1 is an inhibitory serpin with significant sequence homology to α_1 -antitrypsin, antithrombin, and α_1 -antichymotrypsin.^{1382,2082,2083,2084,2085,2086,2087} and²⁰⁸⁸ It shares the fundamental structural plan of these serpins: three β sheets, nine α -helices, and a reactive site loop. PAI-1 is distinguished from the other inhibitory serpins in that it lacks cysteine residues.

The human gene for PAI-1 is located on chromosome 7 bands q21.3-q22 in close proximity to the loci for erythropoietin, paraoxonase, and cystic fibrosis.^{2089,2090} (Table 18.9). It covers 12.2 kb of DNA with nine exons specifying the 23 amino acids of the signal peptide and 379 amino acids of the mature protein.^{2091,2092,2093} and²⁰⁹⁴ Introns, totaling approximately 9,000 bp, define boundaries of individual structural subdomains or are found in random coil regions of the protein.^{2091,2092} The transcription start site is located 25 bp downstream of a consensus TATA sequence.^{2092,2094} The 5'-flanking region of the PAI-1 gene shows an extensive region of nucleotide sequence identity with the 5'-flanking region of the gene encoding t-

PA.^{2093,2094} The 3' region of the human PAI-1 gene contains alternative polyadenylation sites resulting in two mRNA species of different lengths (2.4 and 3.2 kb).²⁰⁹¹

Normal plasma levels of PAI-1 antigen range between 6 and 80 ng/ml. Polymorphisms in the PAI-1 gene appear to correlate with different plasma levels of PAI-1; thus, genotype-specific regulation of PAI-1 accounts for some of the observed variation in the normal population. Nine polymorphisms have been described, with three of these the subject of human population studies.²⁰⁹⁵ A polymorphism located 675 bp upstream of the transcription start site consists of a single guanine insertion/deletion variation (4G/5G) leading to a sequence of four or five guanine nucleotides in the promoter.²⁰⁹⁶ Individuals homozygous for the 4G polymorphism have the highest levels of PAI-1; heterozygotes show intermediate levels; those homozygous for the 5G allele have the lowest levels.^{2097,2098,2099,2100} and ²¹⁰¹ The basis of this differential expression of the PAI-1 gene appears to be the specificity of a transcriptional repressor protein that binds the 5G allele and not the 4G allele.²¹⁰¹ The predictive relationship between the 4G/5G genotype, plasma PAI-1 level, and the risk of thrombosis is controversial.^{2102,2103} and ²¹⁰⁴ The two other polymorphisms investigated both in vitro and in human population studies include an eight-allele (CA)_n repeat in intron 3²¹⁰⁵ and a two-allele Hind III restriction fragment length polymorphism of the 3'-flanking region. Individuals with one of the homozygous genotypes associated with the Hind III site exhibit higher plasma PAI-1 activity than the complementary homozygous individuals.²¹⁰⁵ In vitro studies of the Hind III polymorphism have shown genotype-specific regulation of PAI-1 synthesis by a number of effector molecules.^{2106,2107,2108} and ²¹⁰⁹

Congenital PAI-1 deficiency is a rare disorder, with homozygous PAI-1-deficient individuals showing abnormal bleeding after trauma or surgery.^{2068,2069} A study of an extended family with 19 heterozygotes and 7 individuals homozygous for a null mutation in the PAI-1 gene found no significant developmental or other abnormalities in the homozygotes beyond abnormal bleeding episodes.²⁰⁷¹ Homozygous PAI-1-deficient mice display normal fertility, viability, and development, with no identified histologic abnormalities.^{2110,2111} A mild hyperfibrinolytic state and greater resistance to venous thrombosis were reported. Mice with combined homozygous deficiency of PAI-1 and α_2 -antiplasmin show normal fertility and development while displaying a higher fibrinolytic capacity.²¹¹² However, this increase appears to depend on the α_2 -antiplasmin deficiency alone, suggesting a less critical role for PAI-1 in the regulation of fibrinolysis.

Biochemistry

PAI-1 is a single-chain glycoprotein of 379 amino acids that has no cysteine residues. It is an inhibitory serpin with a reactive

P.492

site bond, Arg³⁴⁶-Met³⁴⁷, positioned in a surface-exposed, disordered loop of 20 amino acids.²⁰⁷⁹ Reaction with t-PA or u-PA involves rapid formation (second-order rate constant = 10^7 to 10^8 M⁻¹second⁻¹) of a reversible complex; specific interactions between a negatively charged region (amino acids 350 to 355) of the PAI-1 molecule and positively charged regions in t-PA^{2113,2114} or in u-PA²¹¹⁵ are important to this initial association. Cleavage of the reactive site Arg³⁴⁶-Met³⁴⁷ bond in PAI-1 by the protease triggers a large conformational change in both the inhibitor and the protease that renders the protease unable to efficiently hydrolyze the normally transient ester linkage between its active site serine residue and the carboxyl moiety of the targeted peptide bond. PAI-1 converts to an inactive (latent) form spontaneously; it can be returned to its active conformation by treatment with denaturants.²¹¹⁶ The crystal structure of latent PAI-1 indicates that the reactive site loop is inserted into the β sheet A of the molecule, making it unavailable to proteases.²¹¹⁷ The crystal structure of a mutant PAI-1 stabilized in the active conformation by substitutions at four sites (N150→H; K154→T; Q319→L; M354→I) shows the reactive site bond to be located at the apex of a flexible, exterior loop.²⁰⁷⁹ The vitronectin binding site of PAI-1 involves five residues located on the exterior of the molecule.²¹¹⁸ Extensive structural differences have been noted when this region is compared in active and latent conformations of PAI-1.²⁰⁷⁹ Stabilization of the conformation of this region of PAI-1 by the PAI-1 vitronectin binding interaction presumably impedes the insertion of the reactive site loop into β sheet A of the molecule.

Function

PAI-1 is the central physiologic inhibitor of the plasminogen activator t-PA in blood. It reacts with both the secreted, singlechain form of t-PA and the two-chain form generated by plasmin during the process of fibrin dissolution. Both PAI-1 and t-PA are characterized by high turnover rates (t-PA, $t_{1/2}$ = 3 to 4 minutes; PAI-1, $t_{1/2}$ = 10 minutes) with functional PAI-1 circulating concentrations maintained at least at severalfold molar excess over the concentration of functional t-PA (14 pmol/L). From the circulating concentration of PAI-1 and the second-order rate constant for the association of PAI-1 with either form of t-PA (10^7 to 10^8 M⁻¹second⁻¹), the predicted $t_{1/2}$ of t-PA is < 1 minute. This is consistent with the observation

that approximately 80% of the t-PA antigen in plasma (70 pmol/L) is found complexed with PAI-1. PAI-1-t-PA complexes have a clearance $t_{1/2}$ of approximately 5 minutes.¹⁸⁵⁴ Although other plasma proteins have been identified in vitro with inhibitory activity toward plasminogen activators (PAI-2, PAI-3, protease nexin), only PAI-1-plasminogen activator complexes have been detected in vivo.^{1127,2119}

PAI-1 is an important inhibitor of u-PA. Unlike t-PA, PAI-1 forms complexes only with the two-chain form of urokinase; it does not complex with the single-chain form of urokinase. The second-order rate constant for the association of PAI-1 and t-PA is in the range of $10^8 \text{ M}^{-1} \text{ second}^{-1}$. Conversion of circulating scu-PA (37 to 74 pmol/L) to t-PA occurs at sites of fibrin lysis. Urokinase is also involved in physiologic and pathologic processes such as embryo development, wound healing, cell migration, inflammation, and metastasis of tumor cells. A large body of in vitro work supports a regulatory role for PAI-1 as a protease inhibitor in u-PA-mediated events outside the vasculature, and as a consequence, its dysregulation has been implicated in the pathogenesis of fibrosis in different organs.²¹²⁰

PAI-1 also appears to be involved in regulating cell adhesion and migration by a mechanism independent of its function as a protease inhibitor. Its high-affinity association with the somatomedin B domain of vitronectin makes it an effective competitor with other ligands such as urokinase-type plasminogen activator receptor (uPAR)^{2121,2122,2123} and ²¹²⁴ and integrins including $\alpha_v\beta_3$ ²¹²⁵ that also bind to vitronectin at this site. The ability to interfere with the binding of such cell-associated ligands to matrix-associated vitronectin suggests a role for PAI-1 as a regulator of the interaction of cells with the extracellular matrix.

Plasminogen Activator Inhibitor-2

PAI-2 is a member of the serpin subfamily designated the ovalbumin-related serpins.²¹²⁶ It was initially identified in human placenta as an inhibitor of urokinase.²¹²⁷ It has also been referred to as the placental-type PAI.^{2127,2128,2129,2130,2131} and ²¹³² It is not normally detected in plasma, although it has been detected in human thrombi.²¹³³ During pregnancy, PAI-2 is found in plasma at levels that may exceed those of PAI-1.²¹¹⁹ PAI-2 appears to have significant functions within the cytoplasm of certain cell types and in the extracellular region outside of the vasculature, where it may regulate urokinase-dependent events. However, its role in hemostasis remains problematic and a definitive intracellular role for PAI-2 is not established.²¹³⁴ PAI-2 (-/-) null mice developed normally and did not display any phenotypic abnormalities.²¹³⁵

Gene Structure and Expression

The gene for PAI-2 is located on chromosome 18, band q22.1, and spans 16.5 kb^{2136,2137,2138,2139,2140} and ²¹⁴¹ (Table 18.9). Its transcript specifies a protein of 415 amino acids that lacks a cleavable NH_2 -terminal signal sequence. PAI-2 is synthesized and secreted by human white blood cells such as monocytes and macrophages, and cells of epithelial lineage such as keratinocytes and certain tumor cells.^{2142,2143,2144} and ²¹⁴⁵ A large number of agonists have been shown to affect transcription rates of the PAI-2 gene (reviewed in ^{2126,2146,2147}). For example, the PAI-2 gene has been shown to respond dramatically to TNF ²¹⁴⁸ and to lipopolysaccharide.²¹⁴⁹ In human monocytes, exposure to lipopolysaccharide induced approximately a 100-fold increase in PAI-2 mRNA levels.²¹⁵⁰ Posttranscriptional regulation of PAI-2 mRNA levels has also been documented.^{2151,2152} Regulation of the stability of PAI-2 mRNA has been shown to derive in part from an AU rich-mRNA destabilizing determinant in the 3'-untranslated region²¹⁵² and from an mRNA instability element identified within exon 4 of the coding region.²¹⁵³

Biochemistry and Function

There are two forms of PAI-2: an intracellular nonglycosylated form ($M_r = 47 \text{ kDa}$) and a secreted glycosylated form ($M_r = 60 \text{ kDa}$) (Table 18.10). However, the nonglycosylated form has been observed in the blood of pregnant women.²¹¹⁹ Glycosylation occurs at Asn^{75} , Asn^{115} , and Asn^{339} . PAI-2 is structurally distinguished from other serpins by the presence of a unique 33-residue-long loop (CD loop: residues 66 to 98) positioned between helices C and D. This solvent-exposed loop region has two glutamine residues (Gln^{83} and Gln^{86}) that have been shown to be sites for factor XIIIa-catalyzed cross-linking of PAI-2 to fibrinogen.^{2133,2154} PAI-2 cross-linked to fibrinogen remains functional after its fibrinogen carrier is converted to insoluble fibrin.²¹⁵⁴ The CD loop has also been implicated in the association of intracellular PAI-2 with other cytoplasmic proteins.²¹⁵⁵ The crystal structure of PAI-2 at 2-Å resolution has recently been reported using a PAI-2 mutant lacking the CD loop.²¹⁵⁶ The reactive site bond ($\text{Arg}^{380}\text{-Thr}^{381}$) is located in a highly disordered reactive center loop extending from Thr^{367} to Pro^{386} . PAI-2 is a serpin inhibitor that can inhibit plasminogen activators. The second-order rate constants defining its interactions with two-chain urokinase ($1 \times 10^6 \text{ M}^{-1} \text{ second}^{-1}$) and two-chain t-PA ($2 \times 10^5 \text{ M}^{-1} \text{ second}^{-1}$) are approximately 100-fold lower than those characterizing the reaction of PAI-1 with these proteases. Unlike PAI-1, PAI-2 reacts very slowly with the single-chain form of t-PA. Also unlike PAI-1, PAI-2-t-PA or PAI-2-u-PA complexes have not been detected in

plasma. Thus, it has been suggested that PAI-2 may not play an important role in regulating intravascular clot lysis. However, fibrin deposition at sites of chronic inflammation within blood vessels may represent an instance in which monocyte-derived PAI-2 could end up cross-linked to fibrin, thereby exerting some effect in the vasculature.^{2133,2154} An extravascular role for PAI-2 in aspects of tissue remodeling and wound healing that depend on urokinase catalysis is consistent with the observed induction of PAI-2 production by inflammatory mediators in cell types such as keratinocytes and macrophages.

The nonglycosylated form of PAI-2 is found in the cytosol of a number of cell types. Data supporting a diverse set of roles for intracellular pools of PAI-2 include effects on cellular differentiation,²¹⁵⁵ cell proliferation,²¹⁵⁷ TNF- α -induced apoptosis,^{2158,2159} signal transduction,²¹⁶⁰ and, in monocytes, multiple roles in modulating adhesion, proliferation, and differentiation.²¹⁶¹

α_2 -Antiplasmin (α_2 -Plasmin Inhibitor)

α_2 -Antiplasmin (or α_2 -plasmin inhibitor) is the primary plasmin inhibitor in human plasma^{2162,2163,2164} and²¹⁶⁵ and thus is an important regulator of fibrinolysis.²¹⁶⁶ Congenital deficiency of α_2 -antiplasmin is rare, with homozygous individuals displaying a severe to moderate bleeding disorder.²¹⁶⁷ α_2 -Antiplasmin is a single-chain glycoprotein with a calculated mass of 58 kDa²¹⁶⁸ and a relative molecular weight of 70 kDa. It is present in plasma at a concentration of 70 mg/L (Table 18.10). The primary site of synthesis is the liver, although the kidney may be another contributing source²¹⁶⁹; its in vivo $t_{1/2}$ is 2.6 days.^{2170,2171} Two NH₂-terminal variants of α_2 -antiplasmin are isolated from human plasma in roughly equivalent amounts: α_2 -antiplasmin Met¹, the full-length protein secreted into the blood; and α_2 -antiplasmin Asn¹, lacking the first 12 amino acids (Asn¹³ in α_2 -antiplasmin Met¹).^{2172,2173} α_2 -Antiplasmin is a member of the serine protease inhibitor superfamily. It forms a stable 1:1 stoichiometric complex with plasmin that has no proteolytic or esterase activity.^{2163,2164,2174} It is structurally distinct from related serpins in having a 55-amino acid extension at its COOH-terminus.^{1466,1467} This region mediates α_2 -antiplasmin binding to specific regions (lysine-binding sites) on the kringle domains of plasminogen and plasmin.^{2175,2176} and²¹⁷⁷ Approximately 30% of α_2 -antiplasmin in human plasma lacks part of this COOH-terminal region (residues 449 to 464). This truncated form appears to be functionally inert in plasma,^{2177,2178} although it has been shown, when purified, to slowly form complexes with plasmin.^{2179,2180}

The α_2 -antiplasmin molecule has three domains defining its role in fibrinolysis: the reactive site (Arg³⁷⁶-Met³⁷⁷), the plasminogen-binding site (both of which are critical to its reactivity with plasmin^{2175,2176,2181}), and a cross-linking site mediating the attachment of α_2 -antiplasmin to the α -chain of fibrin during clotting.¹⁵³¹ The binding of the plasminogen-binding domain of α_2 -antiplasmin to a lysine-binding site of plasmin has been shown to occur more rapidly than the association between the active site of plasmin and the reactive site of α_2 -antiplasmin.²¹⁸² Thus, the rate of binding of α_2 -antiplasmin depends primarily on the availability of the lysine-binding site(s) of plasmin. This dependence of the rate of inhibition on an exosite interaction between the two molecules results in the differential reactivity of α_2 -antiplasmin with its primary targets in clotting blood: plasmin released into the circulating blood ($t_{1/2}$ = 0.1 second) versus plasmin bound through its lysine-binding sites to fibrin or cellular sites at the site of vascular injury ($t_{1/2}$ = 10 seconds).

Gene Structure and Expression

α_2 -Antiplasmin is a member of a multigene family of serine protease inhibitors that includes α_1 -antitrypsin, antithrombin, PAI-1, and α_1 -antichymotrypsin.^{1382,1467,2082} These serpins interact with their target proteases at a reactive Arg-X peptide bond positioned in a loop structure located 30 to 40 amino acids from the inhibitor COOH-terminus. α_2 -Antiplasmin differs from other members of its family in having a 55-amino acid extension at its COOH-terminus.

The human gene for α_2 -antiplasmin is located on chromosome 17, band p13²¹⁸³ and is composed of 10 exons distributed over 16 kb of DNA²¹⁸⁴ (Table 18.9). The 5'-untranslated region and leader sequence are interrupted by three introns; a TATA box sequence is found 17 nucleotides upstream from the transcription initiation site. Exons 4 through 10 code for the protein, with exon 10 specifying both the reactive site and the unique COOH-terminal plasminogen-binding site. One common polymorphism, RGW, has been mechanically linked to differences in the levels of α_2 -antiplasmin Met¹ and α_2 -antiplasmin Asn¹.^{2185,2186}

Congenital α_2 -antiplasmin deficiency has been described²¹⁶⁷; the transmission is autosomal recessive. Bleeding problems vary from severe to moderate in homozygotes. The majority of heterozygotes have no bleeding problems, although exceptions have been described.^{2187,2188} One instance of congenital deficiency, α_2 -antiplasmin Enschede,²¹⁸⁹ is characterized by dysfunctional full-length α_2 -antiplasmin at normal plasma concentrations. All other cases involve quantitative defects with the four characterized instances showing mutations in the coding exons^{2190,2191} and²¹⁹² or an intron splicing donor site²¹⁹³ with consequent truncated, nonsecreted peptide products. Homozygous α_2 -antiplasmin-

deficient mice have been generated.²¹⁹⁴ They display normal fertility, viability, and development, and show no overt bleeding disorder.

Biochemistry

α_2 -Antiplasmin is a single-chain glycoprotein of 464 amino acids with an M_r of 70 kDa (13% carbohydrate; Table 18.10). Glycosylation occurs at Asn⁹⁹, Asn²⁶⁸, Asn²⁸², and Asn²⁸⁹. α_2 -Antiplasmin contains four cysteine residues but only one S-S bridge.²¹⁹⁵ It is a member of the α_1 -proteinase inhibitor class of the serine proteinase inhibitor superfamily.^{1382,1467}

α_2 -Antiplasmin functions as the primary inhibitor of plasmin in blood.²¹⁷⁰ It is synthesized primarily in the liver with a signal peptide of 27 amino acids and circulates at a concentration of 1 $\mu\text{mol/L}$ ²¹⁶⁸ with a $t_{1/2}$ of 2.6 days.^{2170,2171} Isolation from plasma yields both Met¹- α_2 -antiplasmin (464 amino acids) and a truncated form with an NH₂-terminal Asn (Asn¹³- α_2 -antiplasmin)²¹⁷²; the truncated form appears to be generated within circulating blood by a plasma protease.^{2194,2196} Plasma α_2 -antiplasmin is also found to have two COOH-terminal forms: a slow-reacting, non-plasminogen-binding form (30%) that lacks the terminal 26 amino acids and the fully active molecule with an intact COOH-terminal extension.^{2177,2179} Conversion to the non-plasminogen-binding form occurs in the blood.²¹⁷⁸ α_2 -Antiplasmin has three functionally important domains: a reactive site, a plasmin/plasminogen-binding site, and a cross-linking site. The reactive site of the inhibitor is the Arg³⁷⁶-Met³⁷⁷ peptide bond.¹⁴⁶⁶ α_2 -Antiplasmin reacts with plasmin in a two-step process. First, a rapid (second-order rate constant = 2 to 4 $\times 10^7 \text{ M}^{-1} \text{ second}^{-1}$) reversible interaction yields a 1:1 complex ($K_d = 10^{-10} \text{ M}$). Second, a slower first-order ($t_{1/2} = 166$ seconds) covalent bond forms between the active site seryl residue of plasmin and Arg³⁷⁶ of α_2 -antiplasmin with subsequent release of a COOH-terminal fragment (residues 377 to 464) of α_2 -antiplasmin. The plasmin/plasminogen-binding domain is located within residues 410 to 464, with Lys⁴⁶⁴ acting as the key residue.^{2197,2198} and ²¹⁹⁹ It complexes with lysine-binding site(s) located in the kringle structures of plasminogen and plasmin, exhibiting at least a 10-fold stronger binding to plasmin.¹⁸¹³ Lysine-binding sites on kringles 1^{1813,2200} and 4²¹⁹⁵ have been identified as the points of interaction with α_2 -antiplasmin, although their relative importance individually is not resolved.²¹⁹⁵ Maximum rates of α_2 -antiplasmin inhibition of plasmin require the unimpeded interaction of both the plasminogen-binding domain and the reactive

P.494

site of α_2 -antiplasmin with their respective target domains in the plasmin molecule.²¹⁸² Cross-linking of α_2 -antiplasmin at Gln¹⁴ to the α -chain of fibrin is catalyzed by activated factor XIII.²²⁰¹ In vitro, Asn¹³ α_2 -antiplasmin is more efficiently cross-linked to fibrin.^{2196,2202}

Function

α_2 -Antiplasmin is the primary plasmin inhibitor in human plasma. Its effective concentration in plasma is in the range of 0.5 $\mu\text{mol/L}$. Approximately one-third of the circulating pool (1 $\mu\text{mol/L}$) is poorly reactive,^{2177,2179} and another fraction is bound to circulating plasminogen ($K_d = 4 \mu\text{mol/L}$).²¹⁸² α_2 -Antiplasmin stabilizes the fibrin scaffolding of the developing blood clot by attenuating the rate of plasmin-driven fibrinolysis and protects against systemic degradation of fibrinogen and other proteins by plasmin. Fibrin, as the key cofactor for efficient t-PA activation of plasminogen, localizes plasmin generation to the site of fibrin formation. Generated plasmin is partitioned: one fraction is surface associated through binding interactions between its lysine-binding sites and active site and insoluble fibrin; the other fraction mixes with the circulating blood. α_2 -Antiplasmin rapidly inhibits solution phase plasmin ($t_{1/2} \sim 0.1$ second), preventing systemic fibrinogen degradation until more than 50% of its neutralizing capacity has been exhausted.²¹⁷⁰ The in vitro rate of inhibition of fibrin-bound plasmin by α_2 -antiplasmin decreases by at least a factor of 100 ($t_{1/2} \geq 10$ seconds).²²⁰³ This decrease in reactivity reflects the dependence of the rate of inhibition on the availability of both the lysine-binding and active sites of plasmin. Offsetting this, α_2 -antiplasmin is accumulated on fibrin through a factor XIIIa-catalyzed tethering of the NH₂-terminal of α_2 -antiplasmin to the α -chain of fibrin. Approximately 20% of the available α_2 -antiplasmin is rapidly bound to fibrin. This process has been shown to play a significant role in stabilizing the fibrin clot against lysis.^{1774,2204}

PHYSIOLOGIC REGULATION OF FIBRINOLYSIS

The physiologic regulation of fibrinolysis centers on controlling the rate and location of plasmin formation. Under quiescent conditions, there is little systemic plasmin formation. t-PA is a poor catalyst of the conversion of plasminogen to plasmin in the absence of fibrin. In addition, circulating levels of active t-PA are continually suppressed by reactions with PAI-1, thus further reducing the potential for solution phase plasminogen activation by t-PA. scu-PA has negligible activity toward plasminogen in solution. Further, there is no gradual accumulation of plasmin in the blood because the circulating concentration and efficacy of α_2 -antiplasmin limit the $t_{1/2}$ of plasmin formed away from a fibrin surface to 0.1 second. Thus, significant plasmin formation occurs only after the formation of fibrin. t-PA and plasminogen bind to fibrin as the

clot forms, localizing plasmin generation to the clot. Initial plasmin degradation of fibrin actually increases the number of plasminogen-binding sites in the fibrin, thus amplifying plasmin formation rates. Plasmin also cleaves scu-PA to generate the active two-chain form of the catalyst, further enhancing rates of plasmin activation. In addition, fibrin-bound plasmin is protected from inactivation by circulating α_2 -antiplasmin. These mechanisms ensure that plasmin formation is not premature, that plasmin formation is localized to the clot; the extent of plasmin formation is tied to the amount of fibrin present, thus allowing the process to efficiently dissolve thrombi of different sizes.

Regulation of fibrinolysis is achieved through a dynamic balance α_2 between profibrinolytic and antifibrinolytic processes maintained by complex interactions between circulating proteins, clot-based factors, and endothelial cells. Recruitment of the proteins key to fibrinolysis to the site of injury occurs simultaneously with the initiation of fibrin formation. The fibrin clot not only serves as a substrate, but also acts in a role similar to the phospholipid surface in coagulation, functioning as a surface for the activation and localization of fibrinolytic proteins. The association of plasminogen and t-PA with fibrin enhances the rate of plasminogen activation by t-PA. Plasmin bound to fibrin is protected from inhibition by α_2 -antiplasmin.^{2142,2182,2205} These mechanisms both enhance fibrinolysis and serve to limit proteolytic activity to the clot. However, profibrinolytic processes are balanced by antifibrinolytic responses. PAI-1 associates with fibrin and inactivates t-PA and u-PA within the meshwork of the clot.²²⁰⁶ Factor XIIIa crosslinks and stabilizes the fibrin clot and renders it less susceptible to plasmin proteolysis. Factor XIIIa also cross-links α_2 -antiplasmin to fibrin; this incorporation has been shown to play an important role in fibrin clot stabilization.^{1773,1774,2204} TAFIa removes COOH-terminal lysines from partially proteolyzed fibrin, reducing the number of plasminogen-binding sites and attenuating the rate of plasmin formation. In addition, activated platelets release PAI-1 and α_2 -antiplasmin at the fibrin surface, thus supplementing the ongoing downregulation of plasmin levels by the plasma pools of these serpins.^{2207,2208,2209,2210} and²²¹¹

Cellular Regulation of Fibrinolysis

The fibrin clot and, thus, fibrinolysis are localized to the surface of the blood vessel at sites where the normally nonthrombogenic façade presented by the endothelium is either mechanically removed or altered in its molecular composition. The unperturbed endothelium secretes PAI-1²²¹² and is actively antifibrinolytic. Once the endothelial layer is disturbed, α -thrombin is generated, and fibrin formation proceeds at that site.²²¹³ Intact endothelial surfaces in the vicinity of the injury become “activated” via interaction with products of the coagulation cascade, shifting from an antifibrinolytic to a profibrinolytic state. “Activated” endothelial cells express t-PA and u-PA as well as specific receptors for the plasminogen activators.^{2214,2215} and²²¹⁶ t-PA is likely the primary activator of plasminogen at the fibrin surface.^{1914,1987,2217} u-PA has profibrinolytic activity but appears to be primarily associated with extracellular matrix degradation and initiation of tissue repair and remodeling.^{2218,2219} and²²²⁰

In addition to receptors for plasminogen activators, receptors for plasminogen^{2221,2222} have been identified on a number of cell types including platelets, monocytes, fibroblasts, and endothelial cells, in which they appear to localize and accelerate plasmin formation. Plasmin generated at the cell surface is protected from serpin inhibitors by binding to specific cell receptors. Therefore, the cell surface can serve as a sanctuary for plasmin activity.

Urokinase-type Plasminogen Activator Receptor

uPAR is synthesized and expressed by normal and malignant cells including monocytes, neutrophils, fibroblasts, platelets, and endothelial cells.^{2218,2223,2224,2225,2226,2227,2228} and²²²⁹ A primary function of uPAR is to localize u-PA-mediated plasmin generation to the cell surface; however, more generally, uPAR mediates cell migration and tissue remodeling during development and wound healing.^{2230,2231} Thus, uPAR function appears to be enmeshed with coagulation, fibrinolytic, and inflammatory processes.^{2230,2231} and²²³² uPAR binds both singlechain u-PA and plasminogen via high-affinity interactions, forming a ternary complex that enhances plasminogen activation^{2225,2233} and initiates proteolysis of the extracellular matrix.²²³⁴ The receptor is a heterogeneously glycosylated single-chain polypeptide ($M_r = 50,000$ to $60,000$) of 313 amino acids.²²³⁵ Although uPAR is an integral membrane protein, there is no defined transmembrane sequence. uPAR is instead anchored to the cellular membrane by a glycosyl-phosphatidylinositol moiety.²²³⁶ The glycolipid is most likely attached to Gly²⁸³, indicating that

P.495

the mature protein consists of 283 amino acids.^{2236,2237} Because uPAR has no intracellular domain, uPAR mediated signaling presumably occurs through surface interactions with other components of the plasma membrane. At least 9 stable and 33 membrane-associated binding proteins have been identified.²²³⁸ The neutrophils of individuals experiencing the hematopoietic stem cell disorder paroxysmal nocturnal hemoglobinuria, a disease in which these glycosyl-phosphatidylinositol moieties are lacking, show impaired transendothelial migration.^{2227,2239} The absence of the receptor

may play a role in the hypercoagulable state associated with this disorder. The crystal structure of uPAR has been reported in its ligand free form²²⁴⁰ and complexed with sc-UPA.²²⁴¹

Tissue-type Plasminogen Activator Receptors

Many structurally unrelated components that bind t-PA have been described. These receptors can be separated into two distinct functional groups: activation receptors and clearance receptors. Activation receptors are described as localizing t-PA onto a cell surface and enhancing the activation of plasminogen by t-PA.²²⁴² Receptors in the activation category include annexin II (42 kDa),^{2243,2244} heparan sulfate and chondroitin sulfate-like proteoglycans,²²⁴⁵ cytokeratin 8 and 18,^{2246,2247} and tubulin.²²⁴⁸ In patients with promyelocytic leukemia, overexpression of the t-PA receptor annexin II has been associated with a hyperfibrinolytic state resulting in bleeding.²²⁴⁹ The t-PA receptor(s) on endothelial cells is poorly defined (for descriptions of these receptors, see Bachmann¹⁷⁸⁸).

Clearance receptors are responsible for clearing t-PA from the circulation and its subsequent degradation. These receptors control not only the plasma concentration of t-PA but also the levels of inactive t-PA/PAI-1 complexes. t-PA clearance occurs principally in the liver and involves two different receptors: the mannose receptor and the LRP/ α_2 -macroglobulin receptor. The mannose receptor is a major t-PA receptor and binds t-PA with a high-affinity K_d of 1 to 4 nmol/L.^{2250,2251} and²²⁵² Liver endothelial cells and Kupffer cells bind t-PA via the mannose receptor. The other major pathway for t-PA clearance is through the LRP/ α_2 -macroglobulin receptor. This receptor has a relative molecular weight of 600 kDa.¹⁷⁸⁸ This receptor mediates the clearance of t-PA, t-PA/PAI-1, and u-PA/PAI-1 complexes, toxins, cytokines, apolipoprotein E-enriched chylomicron remnants, and complexes of α_2 -macroglobulin.²²⁵³ Free and PAI-1-complexed t-PA have also been shown to be cleared from the circulation through a glycoprotein 330-kDa LRP receptor and a 130-kDa very-low-density lipoprotein receptor.^{2253,2254} and²²⁵⁵

Role of Platelets in the Regulation of Fibrinolysis

Platelets are vital to procoagulant events and contribute to the fibrinolytic process as well. Platelets bind both t-PA and plasminogen and support plasmin generation.^{2256,2257} and²²⁵⁸ Plasmin bound to the platelet surface is also protected from inhibition by α_2 -antiplasmin.²²⁵⁹ Platelets likewise contribute to the antifibrinolytic mechanism. Activated platelets release PAI-1, α_2 -antiplasmin, C1-esterase inhibitor, and α_2 -macroglobulin, which function to inhibit plasminogen activators and plasmin. Therefore, platelets, when present at high concentrations, can promote thrombosis and inhibit fibrinolysis.

Several studies have shown that plasmin can directly modify the function of platelets.^{2259,2260,2261,2262,2263} and²²⁶⁴ When plasmin is present at a low concentration, it can inhibit platelet aggregation by arachidonic acid metabolism or by proteolysis of membrane glycoproteins. At a high plasmin concentration, a proteolytic modification of the platelets occurs that affects fibrinogen binding and platelet aggregation. Plasmin is also able to increase the number of plasminogenbinding sites on the surface of platelets, an alteration that may function as a positive feedback loop for t-PA-mediated plasmin production. Increasing the size of the pool of fibrin-localized, platelet-bound plasminogen would augment the other readily activatable pool (plasminogen bound to fibrin), thereby increasing the amount of plasminogen available for efficient t-PA activation. Plasmin has also been shown to degrade the platelet-binding site for factor XIIIa, decreasing the rate of clot stabilization.²²³³

CONCLUSION

This chapter describes the process of blood coagulation by dividing it into sections based on procoagulant, anticoagulant, and fibrinolytic enzymes, cofactors, and inhibitors in the overall process of fibrin formation and fibrin dissolution. The role of each protein is described as either essential or accessory to hemostasis. The overall process of blood coagulation and fibrinolysis is better described when all the players are considered as contributing to a threshold-limited, complex, intertwined process that together promotes hemostasis.

Our understanding of the coagulation process has ancient historical roots; the accomplishments of numerous clinical and basic investigators have provided a relatively complete description of the inventory, connectivity, and dynamics of the overall process that occurs after vascular injury. Significant progress has been made in achieving a complete set of x-ray crystal structures for all the proteins involved in these processes (Table 18.5). The challenge for the future is the use of this knowledge in the development of new technology for the advancement of diagnosis, prophylaxis, and treatment of vascular disease.

ACKNOWLEDGMENTS

We, the authors, would like to thank Matthew Gissel and Stacia Rymarchyk for their assistance in the preparation of this chapter. This work was supported by an NIH grant (HL46703).

Chapter 19

Endothelium: Angiogenesis and the Regulation of Hemostasis

Paul J. Shami

George M. Rodgers

NORMAL ANGIOGENESIS

Blood circulation requires the production and maintenance of a vast network of vessels that have specialized functions depending on their organ location. The vascular network involves a complex interaction between endothelial cells (ECs), specialized cells such as smooth muscle cells and pericytes, and the extracellular matrix. Vasculogenesis is the de novo development of vessels.¹ It is seen mainly at the embryonic stage of development with the differentiation of a common pluripotent precursor, the hemangioblast, into endothelial and hematopoietic cells. Angiogenesis is the development of new vessels from pre-existing vessels.¹ It is an essential process for wound healing and the maintenance of the integrity of the vascular network. Pathologic angiogenesis is seen in disease states including cancer, retinal, and autoimmune diseases.²

As outlined by Conway, Collen, and Carmeliet,¹ physiologic angiogenesis is a well-organized stepwise process that involves dilation and increased permeability of the parent vessel, dissolution of the extracellular matrix, division and migration of EC, cord formation, and the development of lumina, and, finally, the maintenance of new vessel integrity. The entire process involves the complex and choreographed effects of multiple inducers and inhibitors (Table 19.1).

The first step in angiogenesis is vasodilation. This is mediated through the activation of the soluble guanylate cyclase by nitric oxide (NO).³ NO also up-regulates vascular endothelial growth factor (VEGF) production.⁴ By causing intercellular adhesion molecules to redistribute (platelet-EC adhesion molecule-1 and VE-cadherin, among others), VEGF induces an increase in vascular permeability.^{5,6} The VEGF-induced increase in vascular permeability is negatively controlled by angiopoietin-1 (Ang1) through its receptor, Tie2.⁷ The next key step to vascular development is the dissolution of the extracellular matrix, which is accomplished by proteases belonging to the matrix metalloproteinase family.^{8,9} These proteases also induce the liberation of EC growth factors from the extracellular matrix, including VEGF and basic fibroblast growth factor. The action of matrix metalloproteinases is negatively controlled by a family of protease inhibitors, including the tissue inhibitors of metalloproteinases.¹⁰

Degradation of the extravascular matrix allows the development of the key element of the angiogenesis process, namely, EC division and migration. The list of factors that stimulate this process is extensive (Table 19.1), but a key role is played by VEGF in concert with Ang1.^{6,11,12,13,14,15} and¹⁶ Angiopoietin-2 (Ang2) could have angiogenic effects in the presence of VEGF, whereas it is antiangiogenic in the absence of VEGF.^{14,15,16} and¹⁷ The role played by the endothelial NO synthase and NO has been the subject of controversy, with reports showing that NO has both pro- and antiangiogenic effects.^{18,19,20,21} Other factors that stimulate angiogenesis include basic fibroblast growth factor and platelet-derived growth factor.^{22,23,24} EC growth is negatively controlled by endogenous angiogenesis inhibitors that include angiostatin, endostatin, interferons, and antithrombin.^{25,26,28} ECs then migrate in large part through the action of integrins ($\alpha_v\beta_3$ and $\alpha_v\beta_1$).²⁹ The end result of EC division and migration is sprouting and the formation of cords.¹ This is followed by lumen formation, which is controlled by different VEGF isoforms, Ang1, and integrins.^{1,15} Thrombospondin-1 acts as an endogenous inhibitor of lumen development.¹

Once formed, new vessels survive for years.¹ This prolonged survival is maintained by the interaction of VEGF with its receptor VEGFR-2, phosphoinositide 3-kinase, β -catenin, and VE-cadherin.^{1,30} The angiopoietins also play a role in maintaining vessel survival through their receptors Tie1 and Tie2. Ang1 stabilizes the vessel, whereas Ang2 has an opposite effect^{14,15,31} (see later). An essential element in the maintenance of the integrity of vessels is their "coating" with smooth muscle cells and pericytes.³² Evidence suggests that vascular smooth muscle cells and ECs have a common precursor.³³ On stimulation with platelet-derived growth factor-BB, these precursor cells differentiate into smooth muscle cells, whereas VEGF stimulation drives them to differentiate into EC.³³ Besides providing physical support for endothelial vessels, smooth muscle cells and pericytes are a source of factors that are important for the maintenance and control of

vascular integrity and function.^{1,32} The extracellular matrix plays a key role in that respect by being a dynamic storage site for growth factors and proenzymes that are important in vessel function and angiogenesis.¹

Vascular Endothelial Growth Factor and Its Receptors

VEGF is the pivotal factor controlling angiogenesis. As such, it is the best-studied angiogenic factor. Several proteins belong to the VEGF family and include VEGF (also known as VEGF-A), VEGF-B, VEGF-C, VEGF-D, and placental growth factor.¹⁴ Although VEGF-A is the main angiogenic factor discussed here, VEGF-B seems to play an important role in coronary vascular development.³⁴ VEGF-C is essential for lymphangiogenesis by interacting with the VEGFR-3 receptor.³⁵ The function of VEGF-D has yet to be determined.¹⁴

Being the major regulator of angiogenesis, VEGF is a mitogen and survival factor for EC.^{11,14} As mentioned earlier, it is also a potent inducer of vascular permeability, an essential step in the angiogenic process.^{1,11,14} It has two well-characterized receptors, VEGFR-1 and VEGFR-2 (also known as Flt-1 and Flk-1/kinase domain receptor, respectively).¹⁴ They are both tyrosine kinases. VEGFR-2 is the main effector of a VEGF-induced chemotactic and mitogenic response in EC. VEGFR-2 also mediates the ECs' permeability effects.¹⁴ The role of VEGFR-1 in EC response to VEGF has not been totally elucidated. However, it seems to negatively control the VEGF effects by acting as a decoy.^{14,36,37} Indeed, mice that have been engineered not to express VEGFR-1 have evidence of excess and disorganized angiogenesis.³⁶ In addition to its role in angiogenesis, VEGF has been shown to be trophic for nerve cells, lung epithelial cells, and cardiac muscle fibers.³⁸

Angiopoietins and Their Receptors

Angiopoietins and Tie receptors play an important role in angiogenesis. To date, four angiopoietins have been identified.¹⁴ However, only Ang1 and Ang2 have been fully characterized. They interact with the Tie tyrosine kinase receptors, mainly Tie2. Ang1 plays an important role in stabilizing the vasculature.¹⁴ Supportive cells express Ang1 and interact with EC through the Tie2 receptor. Genetically engineered mouse embryos that lack Ang1 develop a normal primary vasculature. However, they do not undergo further vascular remodeling.¹⁶ Transgenic mice that

P.499

overexpress Ang1 have evidence of vascularization characterized by larger vessels rather than a greater number of vessels.¹⁵ Additionally, those vessels are resistant to leak, further supporting the role of Ang1 as a stabilizing factor.

TABLE 19.1 ACTIVATORS AND INHIBITORS OF ANGIOGENESIS

Activators	Function	Inhibitors	Function
VEGF, VEGF-C, PIGF, and homologs	Stimulate angiogenesis, permeability; stimulate lymphangiogenesis, pathologic angiogenesis	VEGFR-1, soluble VEGFR-1, and NP-1	Sink for VEGF, VEGF-B, PIGF (VEGFR-1), and VEGFR ₁₆₅ (NP-1)
VEGFR	VEGFR-2: angiogenic signaling; VEGFR-3: (lymph) angiogenic signaling	Ang2	Ang1 antagonist; induces vessel regression in absence of angiogenic signals
Ang1 and Tie2 receptor	Ang1: stabilizes vessels, inhibits permeability	TSP-1	ECM proteins; inhibits EC migration, growth, and adhesion
	Ang2: destabilizes vessels before sprouting	TSP-2	Inhibits angiogenesis
Platelet-derived growth factor-BB and receptors	Recruit smooth muscle cells	Meth-1, Meth-2	Contains metalloprotease, thrombospondin, and disintegrin domains
TGF- β_1 , endoglin,	Stabilize vessels by stimulating Angiostatin and related		Inhibits EC survival

TGF- β receptors	ECM production	plasminogen kringle	and migration
Fibroblast growth factor, hepatocyte growth factor, monocyte chemotactic protein-1	Stimulate angiogenesis, stimulate arteriogenesis	Endostatin	Inhibits EC survival and migration
Integrins $\alpha_V\beta_3$, $\alpha_V\beta_5$	MMP receptors	Vasostatin, calreticulin	Inhibits EC growth
VE-cadherin, platelet-EC adhesion molecule	EC junctional molecules, promote EC survival	Platelet factor-4	Heparin-binding molecule; inhibits binding of bFGF and VEGF
Ephrins	Regulate arterial/venous specifications	Tissue inhibitors of metalloproteinases, MMP inhibitors	Suppresses pathologic angiogenesis
		Proteolytic fragment of MMP	Inhibits binding of MMP2 to $\alpha_V\beta_3$
Plasminogen activators, MMPs	Cell migration and matrix remodeling; liberate bFGF/VEFG from ECM; activate TGF- β_1 ; generate angiostatin		
Plasminogen-activator inhibitor-1	Stabilizes nascent vessels (prevents ECM dissolution)	IFN- α , - β , - γ ; IL-4, -12, -18	Inhibits EC migration, IFN- α down-regulates bFGF
Nitric oxide synthase, cyclo-oxygenase-2	Nitric oxide/prostaglandins stimulate angiogenesis and vasodilation	Prothrombin kringle 2 antithrombin fragment	Suppresses EC growth
AC133	Angioblast differentiation	Prolactin fragment; secreted protein (acidic and rich in cysteine) fragment	Inhibits bFGF and VEGF; inhibits EC binding and activity of VEGF

Ang, angiopoietin; bFGF, b-fibroblast growth factor; EC, endothelial cells; ECM, extracellular matrix; IFN, interferon; IL, interleukin; Meth, metalloproteinase and thrombospondin; MMP, matrix metalloproteinase; NP, neuropilin; PlGF, placental growth factor; TGF, transforming growth factor; TSP, thrombospondin; VEGF, vascular endothelial growth factor; VEGFR, vascular endothelial growth factor receptor.

Adapted from Conway EM, Collen D, Carmeliet P. Molecular mechanisms of blood vessel growth. *Cardiovasc Res* 2001;49:507-521.

The function of Ang2 has been more difficult to characterize.^{14,17} It too binds with high affinity to the Tie2 receptor. Transgenic overexpression of Ang2 in mice is embryonically lethal and induces a phenotype that is similar to Ang1 or Tie2 knockout experiments. Thus, it has been suggested that Ang2, by acting as an antagonist of Tie2, negates the stabilizing effects of Ang1 on the vasculature. As such, Ang2 may be a destabilizing factor that helps initiate angiogenesis and vascular remodeling.¹⁴

NOTCH Signaling

Carmeliet and Jain have proposed a model for vessel development whereby in the angiogenesis process, ECs can be divided into two categories, namely tip cells and stalk cells.³⁹ Tip cells migrate and lead vessel development whereas stalk cells divide. The process is controlled by the NOTCH signaling pathway. VEGF activation of VEGFR-2 leads to up-regulation of DLL4 in tip cells. DLL4 then activates NOTCH in stalk cells. NOTCH down-regulates VEGFR-2 and up-regulates VEGFR-1 in stalk cells, making them less sensitive to VEGF-stimulated sprouting. The end result is to maintain the lead of tip cells in vessel development.⁴⁰ However, NOTCH stimulates stalk cell proliferation in vivo through activation of WNT signaling.⁴¹ NOTCH up-regulates its own inhibitor Nrarp in stalk cells.⁴² It has been observed that the tip cell position is dynamic with stalk cells moving into the tip position depending on modulation of VEGFR-1 and VEGFR-2 expression.^{39,42}

Origin of Endothelium

Asahara et al. have shown that human buffy coat cells can differentiate into cells expressing endothelial markers, including VEGFR-1, VEGFR-2, and CD31.⁴³ This raises the possibility that circulating endothelial stem cells can be recruited to sites of angiogenesis. This may be particularly relevant for tumor angiogenesis,

P.500

whereby tumors can develop their vasculature both from recruitment of local endothelium and circulating endothelial stem cells.⁴⁴ Factors involved in the recruitment of endothelial stem cells may include stromal cell-derived factor-1, thrombopoietin, and soluble kit ligand.⁴⁴

Angiogenesis in Normal and Malignant Hematopoiesis

There is mounting evidence suggesting the presence of a common precursor for ECs and hematopoietic cells.⁴⁵ This hemangioblast gives rise to both ECs and hematopoietic cells in embryonic development. Embryonic stem cells express VEGFR-2 and can give rise, depending on culture conditions, to hematopoietic progenitor cells and angioblasts.⁴⁵ Stimulation of hematopoietic stem cells with growth factors, including kit ligand, interleukin-3, granulocytemacrophage colony-stimulating factor, and granulocyte colony-stimulating factor, induces the release by those cells of VEGF, which then induces the release of hematopoietic growth factors by bone marrow ECs.⁴⁵ Thus, there is a dynamic interaction between hematopoietic and endothelial elements in the bone marrow. This interaction seems to modulate, at least in part, hematopoiesis.

Several studies have shown evidence of increased angiogenesis in hematopoietic malignancies.⁴⁶ Such evidence has been demonstrated in multiple myeloma and lymphomas, as well as in acute and chronic leukemias.^{46,47,48,49,50,51,52} and ^{53,55,56} Malignant hematopoietic cells have been shown to produce angiogenic factors, including VEGF.⁴⁶ Expression of angiogenic factors has been suggested to have prognostic significance in hematopoietic malignancies, although results have been variable.⁴⁶ Similar to the effect observed in normal hematopoiesis, VEGF stimulates the production of hematopoietic growth factors by ECs.⁴⁶ Consequently, malignant cells exploit their environment to their advantage by developing a synergistic relationship with ECs (Fig. 19.1). This has led to the active investigation of antiangiogenic agents as a novel therapeutic strategy for hematologic malignancies.

In addition to the effects of vascular endothelium in modulating and responding to angiogenic stimuli, vascular endothelium also influences other functions,^{56,57} including vasoconstriction, selective permeability, hemostasis, antigen presentation, and the inflammatory response. The EC surface is a dynamic interface between soluble and cellular constituents of the blood and the remainder of the body.⁵⁸ A brief discussion of ECs structure and regulation of hemostasis follows.

FIGURE 19.2. Relationship of vascular surface area to volume in the vascular system. Diameters are plotted from published data. (From Rushmer RF. Properties of the vascular system. In: Cardiovascular dynamics. Philadelphia, PA: WB Saunders, 1976. Modified from reference 59, with permission.)

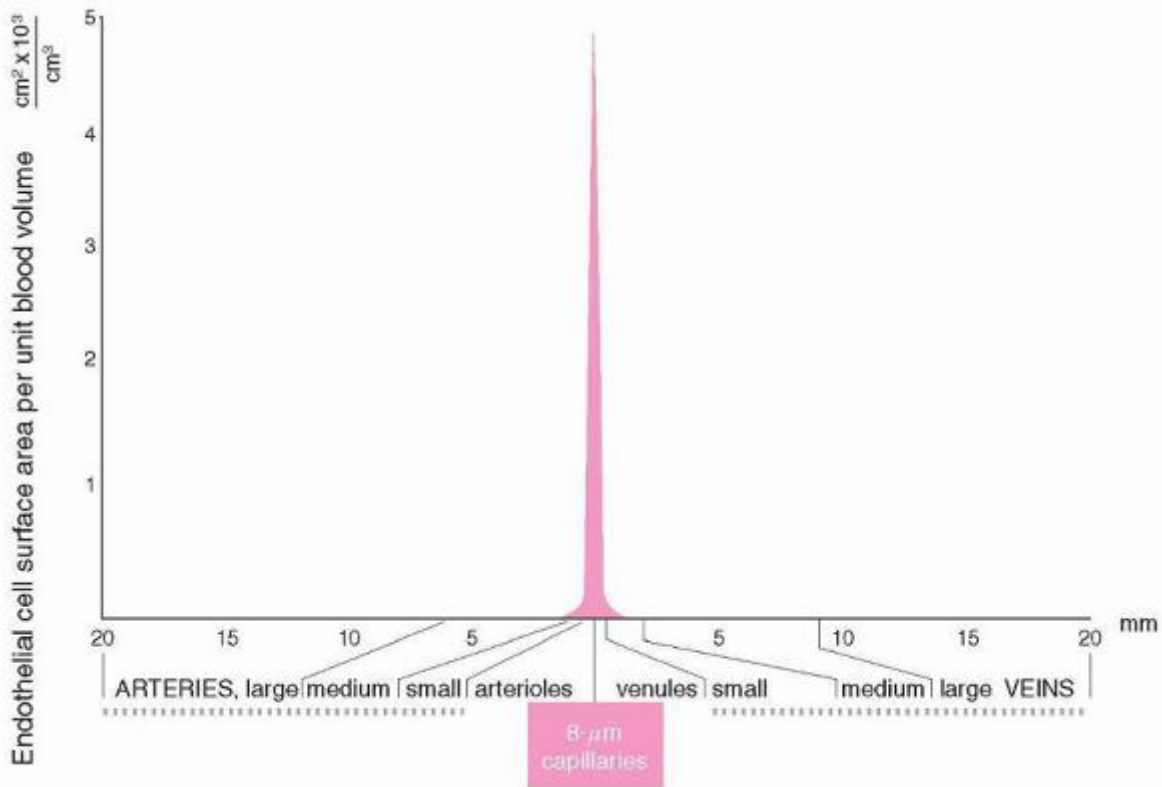

FIGURE 19.1. Hypothesis for the role of angiogenesis in leukemia. (1) Angiogenic factors (AFs) produced by leukemic cells can stimulate cell growth and invasion, or inhibit apoptosis (autocrine mechanism). (2) AFs produced by leukemic cells can also stimulate endothelial cell proliferation and the production of endothelial cell hematopoietic growth factors (HGFs)

(paracrine mechanism). AFR, angiogenic factor receptor; HGFR, hematopoietic growth factor receptor. (From Dickson DJ, Shami PJ. Angiogenesis in acute and chronic leukemias. *Leuk Lymphoma* 2001;42:847-853, with permission.)

ENDOTHELIAL CELL STRUCTURE

Individual ECs measure approximately 20 to 50 μm^2 in surface area. The total vascular surface area in a normal adult is estimated to be at least 4,000 m^2 .⁵⁸ However, the geometry of the vascular system is not static. As indicated in Figure 19.2, the surface area facing a unit volume of blood differs, depending on the vascular bed being considered. For example, the surface areato-volume ratio is approximately 1,000 times greater in capillaries than in large blood vessels.⁵⁹ This vascular geometry has implications for regulation of hemostasis and is discussed later.

P.501

ECs are anchored to the vessel wall by basement membrane secreted by ECs and smooth muscle cells. Basement membrane contains a large number of connective tissue components, including collagen, microfibrils, glycosaminoglycans (GAGs), fibronectin, and thrombospondin. These components may serve as ligands for a number of cell adhesion processes that are important in angiogenesis, hemostasis, vascular repair, and inflammation.^{57,60}

ECs typically exist as a cell monolayer, exhibiting contact inhibition and a cobblestone appearance (Fig. 19.3). Two types of cell-cell junctional structures have been reported: adherens junctions and tight junctions. These structures regulate permeability and maintain polarity.⁶¹ Two cell receptors thought to be important in EC monolayer organization are platelet-EC adhesion molecule-1⁶² and vascular cadherin.⁶³ CD146 (MelCAM) is associated with the EC cytoskeleton and likely serves as an EC junction component.⁶⁴ Members of the junctional adhesion molecule family appear to be components of tight junctions.⁶⁵

ECs contain unique intracellular structures called Weibel-Palade bodies⁶⁶; these organelles contain the adhesion protein von Willebrand factor, which is secreted constitutively and also in response to cell stimulation.⁶⁷ The Weibel-Palade body membrane contains P-selectin, which is expressed on the EC surface after EC activation. When expressed on the vascular surface, P-selectin mediates neutrophil and monocyte adhesion to the vessel wall.⁶⁸ Selectin-independent platelet adhesion to endothelium has also been reported.⁶⁹ The role of P-selectin in inflammation and thrombosis is being increasingly recognized.⁷⁰ Integrins mediating platelet-EC and leukocyte-EC interactions are discussed in Chapters 17 and 7, respectively. Additional EC proteins have been reported to undergo regulated release or cell-surface expression, including tissue plasminogen activator (TPA), interleukin-8, endothelin-1, and multimerin.⁷¹ These and other proteins may be contained in Weibel-Palade bodies or other distinct organelles. The regulated secretion of these EC proteins has been reviewed.⁷¹

Endothelial Cell Phenotypes: Resting versus Activated

The concept of differing EC phenotypes (e.g., resting [constitutive] vs. activated) has been applied to numerous EC functions,⁷² including the inflammatory response, regulation of coagulation, and angiogenesis. This chapter focuses on EC phenotypes as related to the functions of angiogenesis, and hemostasis and thrombosis. Other EC functions have been reviewed elsewhere.^{57,72}

FIGURE 19.3. Endothelial cell morphology. A: Cultured human umbilical arterial endothelial cells with the typical cobblestone appearance (phase-contrast, $\times 100$). B: Scanning electron photomicrograph of a primate aorta. The bar indicates a distance of 100 μm . (From Faggitto A, Ross R, Harker L. Studies of hypercholesterolemia in the nonhuman

primate. I. Changes that lead to fatty streak formation. *Arteriosclerosis* 1984;4:323-340, with permission of the American Heart Association.)

THE VESSEL WALL AND HEMOSTASIS: GENERAL CONCEPTS

The three major cell types of the normal vessel wall are ECs (intima), smooth muscle cells (media), and connective tissue elements, such as fibroblasts (adventitia). The circulating coagulation proteins contained in the blood are in immediate contact with quiescent vascular endothelium that normally presents a thromboresistant surface in that ECs are unable to initiate coagulation^{73,74} or promote platelet adhesion and activation.^{75,76,77} and ⁷⁸ Thus, in the absence of vascular trauma or perturbation (activation), blood remains fluid as a result of antithrombotic activities expressed by ECs. However, after traumatic vascular injury, exposure of blood to cells within the vessel wall, especially fibroblasts, or to extracellular matrix (subendothelium) results in rapid initiation of coagulation because fibroblasts⁷³ and subendothelium containing EC remnants⁷⁹ constitutively express tissue factor (TF) procoagulant activity. Alternatively, perturbation (activation) of EC by stimuli, such as cytokines,⁸⁰ may induce altered EC hemostatic function (in the absence of vascular injury), resulting in net EC expression of thrombotic activity. These hemostatic properties of unperturbed and perturbed EC are critical in determining the coagulant balance of the vessel wall and the extent of activation of coagulation.

A cell-based model of hemostasis has been presented in which fibroblasts or perturbed EC express TF to initiate coagulation; amplification and propagation of coagulation then occur on the platelet surface. Modulation of coagulation occurs via EC antithrombotic activities and plasma protease inhibitors.⁸¹

ANTITHROMBOTIC PROPERTIES OF UNPERTURBED ENDOTHELIUM

Antithrombotic mechanisms responsible for unperturbed (native) EC thromboresistance are illustrated in Figure 19.4. Major antithrombotic properties can be classified as antiplatelet activities, anticoagulant activities, and fibrinolytic activities.

Antiplatelet Activities

Vascular endothelium inhibits platelet function by several mechanisms. The EC plasma membrane does not permit adherence of resting platelets.⁸² Additionally, ECs synthesize and secrete three potent antiplatelet agents: prostacyclin (PGI₂), NO, and certain

P.502

adenine nucleotides. PGI₂ is constitutively synthesized by EC cyclo-oxygenase (prostaglandin H synthase) and phospholipase A₂ in response to thrombin⁸³ and other vasoactive agonists.⁸⁴ In addition to PGI₂'s ability to prevent adhesion of activated platelets to EC, this agent also possesses potent vasodilating properties.⁷⁶ PGI₂ inhibits platelet function by increasing levels of platelet cyclic adenosine monophosphate. Aspirin inhibits the synthesis of PGI₂ by irreversibly acetylating and inactivating EC cyclo-oxygenase.⁸⁵ Recovery of PGI₂ production by EC occurs with subsequent EC synthesis of cyclo-oxygenase.

FIGURE 19.4. Vessel wall antithrombotic properties. The major antithrombotic properties are depicted in boxes. Heparinlike glycosaminoglycans (GAG), such as heparan sulfate, catalyze inactivation of serine proteases, such as thrombin (T) and factor Xa, by antithrombin (AT). Formation of the T-thrombomodulin complex activates protein C to activated protein C (APC). The endothelial cell (EC) protein C receptor (ECPCR) promotes protein C activation. Binding of APC to EC-bound protein S (and factor V) promotes proteolysis of factors Va and VIIIa (dashed line), inhibiting coagulation. APC also possesses anti-inflammatory properties that are mediated by EC protease-activated receptor (PAR)-1. This APC activity requires ECPCR (not shown). Secretion of vessel wall prostacyclin (PGI₂) and nitric oxide and expression of CD39 limit platelet thrombus formation at sites of vascular injury. Tissue plasminogen activator (TPA) is secreted and bound to EC to initiate fibrinolysis. Secretion of tissue factor pathway inhibitor (TFPI) by EC suppresses tissue factor-mediated initiation of coagulation. Dermatan sulfate-catalyzed activation of heparin cofactor II and an inhibitor to contact activation are not illustrated in the figure. FDP, fibrin degradation products. (Modified from Rodgers GM. Hemostatic properties of normal and perturbed vascular cells. *FASEB J* 1988;2:116-123.)

A second inducible form of cyclo-oxygenase, called cyclooxygenase-2, has been identified in a variety of cells, including ECs.^{86,87} Both cyclo-oxygenase proteins are homologous, with similar molecular weights and structural features. Investigators believe that cyclo-oxygenase-2 mediates the vascular response to injury and inflammation.

NO is thought to be important primarily in regulating vascular tone,^{88,89} although this agent is also a potent inhibitor of platelet adhesion to vascular endothelium.⁷⁷ Constitutive and inducible pathways generate NO from the terminal guanidino nitrogen of arginine in a reaction catalyzed by NO synthetase.^{88,90} The constitutive mechanism generates small amounts of NO and mediates physiologic responses. Increased synthesis of NO occurs in response to cytokines (inducible pathway), such as tumor necrosis factor, to mediate inflammatory events.⁸⁹ Both the constitutive and inducible forms of NO synthetase are present in ECs. Other stimuli to NO generation include adenosine diphosphate (ADP), thrombin, shear stress, and bradykinin.⁵⁷ EC-derived NO also inhibits leukocyte adhesion, as well as vascular smooth muscle cell

proliferation. Elevated levels of cyclic guanosine monophosphate result from NO stimulation and mediate the biologic activities of this antiplatelet agent. Synthesis of NO is insensitive to the effects of aspirin.

A third EC antiplatelet property is ectoenzymes that rapidly metabolize ADP and adenosine triphosphate to adenosine monophosphate and adenosine.⁹¹ ADP is a potent platelet agonist, and adenosine is a potent inhibitor of platelet function. Thus, ECs can convert a platelet agonist to an antiplatelet agent by this mechanism. EC ectoenzymes are insensitive to the effects of aspirin. This ectoenzyme antiplatelet property of EC may explain earlier reports of EC thromboresistance to platelet adhesion. The EC ecto-ADPase responsible for inhibition of platelet function is CD39.⁹² Deletion of this EC receptor in mice results in a prothrombotic state and platelet dysfunction.⁹³

Anticoagulant Activities

Vascular ECs synthesize and express heparinlike GAG, such as heparan sulfate and dermatan sulfate, on their luminal surface.⁹⁴ These GAGs catalyze the inactivation of serine proteases, such

P.503

as thrombin and factor Xa, by protease inhibitors, such as antithrombin and heparin cofactor II, respectively, via formation of a covalent protease-antiprotease complex. Of these two protease inhibitors, antithrombin is considered to be more important.⁹⁵ The molecular basis for the effect of heparin in promoting antithrombin neutralization of serine proteases involves interaction of a specific pentasaccharide sequence of the EC heparinlike molecule with an allosteric site on the antithrombin molecule.^{94,95} This interaction results in conformational changes in antithrombin that permit more efficient binding to and inhibition of protease molecules. In vivo, antithrombin molecules are associated with EC GAG,⁹⁴ providing a mechanism for instantaneous control over activation of coagulation. Surprisingly, mice deficient in the enzyme responsible for generating the pentasaccharide activity do not show a procoagulant phenotype.⁹⁶ Nevertheless, this heparan sulfate-antithrombin mechanism is considered to be an important natural anticoagulant process because deficiency of antithrombin in humans is associated with a thrombotic tendency.⁹⁷ In contrast, the clinical relevance of the heparin cofactor II mechanism is uncertain.⁹⁸

Another key vascular anticoagulant activity is the protein C pathway that consists of two plasma proteins—protein C and protein S—and an EC receptor, thrombomodulin (Fig. 19.4). ECs synthesize and express protein S⁹⁹ and thrombomodulin,¹⁰⁰ whereas protein C is synthesized by the liver. Thrombin generation leads to thrombin's binding to thrombomodulin; the thrombin-thrombomodulin complex then activates protein C to generate activated protein C (APC).¹⁰¹ APC binds to protein S, resulting in inhibition of coagulation by proteolysis of two coagulation cofactor proteins, factors Va and VIIIa. Inactivation of factors Va and VIIIa prevents further thrombin formation. The involvement of factor V in mediating the anticoagulant effect of APC has been described.¹⁰² It appears that APC down-regulation of coagulation (proteolysis of factors Va and VIIIa) occurs more efficiently on vascular endothelium rather than on platelets.¹⁰³

An additional component of the protein C pathway exists: the EC protein C receptor (ECPCR). This protein binds protein C to enhance protein C activation by the thrombin-thrombomodulin complex.^{104,105} ECPCR is found primarily on large-vessel endothelium¹⁰⁶ and is induced by thrombin stimulation. Blocking ECPCR with a monoclonal antibody in a primate model indicates that ECPCR plays a major role in in vivo protein C activation.¹⁰⁷

Certain components of the protein C pathway possess additional anticoagulant activities. For example, APC also possesses profibrinolytic activity that results from the ability of APC to neutralize plasminogen-activator inhibitor-3 (PAI-3) activity.¹⁰⁰ Thrombomodulin may also inhibit factor Xa.¹⁰⁸ An additional antithrombotic activity of protein S has been described as inhibition of TF activity by enhancing the interaction between TF pathway inhibitor (TFPI) and factor Xa.¹⁰⁹ Recurrent thrombosis has been associated with deficiency or abnormality of the protein C pathway components, indicating that this anticoagulant mechanism is relevant for in vivo hemostasis.

APC possesses activities other than those associated with anticoagulant activity. In gene-expression studies using microarray techniques, APC was found to modulate anti-inflammatory and cell-survival pathways. APC suppressed adhesion molecule expression, decreased activity of the nuclear factor- κ B transcription pathway, and inhibited apoptosis.¹¹⁰ Recent information suggests that APC uses the ECPCR to signal EC via the protease-activated receptor (PAR)-1 pathway (discussed later).¹¹¹

Regulation of TF procoagulant activity by a plasma protein called TFPI has been described.^{112,113,114} This protein is synthesized primarily by EC¹¹⁵ and is an important regulator of TF-factor VIIa activation of factor X (discussed in Chapter 18). Additionally, TFPI can inhibit vascular cell proliferation.¹¹⁶ TFPI may be important for in vivo hemostasis because administration of this inhibitor in the setting of TF-induced disseminated intravascular coagulation reduces thrombosis.¹¹⁷

and low levels of TFPI are a risk factor for thrombosis.¹¹⁸ Heparin or low-molecular-weight heparin releases TFPI from EC storage sites.¹¹⁹

Fibrinolytic Activities

ECs synthesize and secrete plasminogen activators, primarily TPA, in response to stimulation by thrombin or vasoactive stimuli, such as histamine and vasopressin.¹²⁰ TPA has been localized to the Weibel-Palade organelles in EC.¹²¹ Specific EC receptors for TPA exist.¹²² In response to inflammatory mediators, ECs synthesize another plasminogen activator, urokinase,¹²³ which activates plasminogen in the fluid phase or bound to fibrin. Activation of plasminogen by TPA generates plasmin; localization of TPA and plasminogen to the fibrin clot leads to physiologic fibrinolysis and release of soluble fibrin degradation products (Fig. 19.4). Fibrin degradation products possess potent antiplatelet and antithrombin activities and contribute to the anticoagulant effect of fibrinolysis. Activation of plasminogen is regulated by PAIs. The major inhibitor of TPA is PAI-1; PAI-1 is secreted by vascular EC¹²⁴ but is also present in platelet α -granules.¹²⁵ This inhibitor also regulates urokinase activity.¹²⁶ PAI-2 is a less significant inhibitor of TPA that is found primarily in placenta.¹²⁶ Details of the fibrinolytic mechanism and its regulation are discussed in Chapter 18.

PROTHROMBOTIC PROPERTIES OF UNPERTURBED ENDOTHELIUM

Unperturbed ECs possess procoagulant activities that promote coagulation after vascular injury or perturbation.⁸⁰ However, in the absence of initiating stimuli, these activities remain latent and do not contribute to thrombosis. Major prothrombotic activities of resting EC include binding sites (receptors) for coagulation zymogens or proteases (factor XII,¹²⁷ factor XI,¹²⁸ factors X and Xa,^{129,130,131,132} factors IX and IXa,^{129,133,134} and thrombin¹³⁵) and cofactor proteins [high-molecular-weight kininogen,¹³⁶ factor VIIIa,¹³⁴ and factor Va¹³⁷] and synthesis and expression of factor V^{138,139} and von Willebrand factor.¹⁴⁰ Resting ECs can also activate bound factor XII and promote functional cleavage of prekallikrein.¹²⁷ Investigators have also reported a factor XII-independent pathway for prekallikrein activation on EC; this activation is mediated by an EC-associated thiol protease.¹³⁶ In addition, when high-molecular-weight kininogen is bound to EC, factor XI (XIa) can associate with EC to promote factor IX activation.¹⁴¹ On the other hand, ECs also secrete an inhibitor to contact activation.¹⁴² The role of EC in activation of intrinsic coagulation has been reviewed.¹⁴³ These prothrombotic activities are illustrated in Figure 19.5.

EC receptors for coagulation proteases permit assembly of complexes consisting of cofactor proteins, proteases, and zymogen substrates that result in optimal activation and localization of coagulation.¹⁴⁴ Whereas factor V is secreted primarily into the fluid phase,¹³⁸ von Willebrand factor is secreted both into plasma and the subendothelium, providing a source of adhesive protein for the platelet response to vascular injury.¹⁴⁵

HEMOSTATIC PROPERTIES OF PERTURBED ENDOTHELIUM

In this discussion, the term EC perturbation means exposure of EC to diverse stimuli, such as traumatic vascular injury, certain cytokines, atherogenic stimuli (homocysteine, modified low-density lipoprotein [LDL]), lipopolysaccharide (endotoxin), immune complexes, and certain infectious organisms. From this list, it is obvious that a variety of inflammatory, infectious, or malignant

P.504

disorders, as well as metabolic defects, may be associated with hemostatic dysfunction resulting from altered EC hemostatic properties. With the exception of traumatic vascular injury, alteration of these key EC coagulant properties is not associated with cytotoxicity or EC desquamation. The major hemostatic properties reviewed in this section include TF activity, thrombomodulin activity (protein C pathway), factor V activation, and fibrinolytic activities (TPA, PAI-1). In general, these activities are concordantly regulated, with stimuli that induce TF expression also suppressing protein C activation and fibrinolysis. The net result of these events is that the perturbed EC surface is converted from an antithrombotic surface to a prothrombotic surface.

FIGURE 19.5. Vessel wall prothrombotic properties. The major prothrombotic properties are depicted in boxes. Expression of tissue factor activity initiates coagulation, and endothelial cell (EC) synthesis of factor V promotes thrombin formation. Thrombin formation is enhanced by feedback activation of factor XI. Vessel wall injury also promotes platelet adhesion and thrombus formation by exposure of subendothelial von Willebrand factor (VWF). An inducible EC prothrombin activator may directly generate thrombin. EC can be induced to express an activator of factor V (Va). Thrombin exerts multiple procoagulant activities, including platelet activation and cleavage of fibrinogen, resulting in the fibrin clot. Thrombin binding to thrombomodulin activates thrombin-activatable fibrinolysis inhibitor to down-regulate fibrinolysis (not shown). EC secretion of tissue plasminogen activator (TPA) inhibitor further stabilizes the fibrin clot by preventing fibrinolysis. Also not shown are EC-binding sites for coagulation zymogens or proteases. Protease-activated receptor (PAR)-2 is activated by the tissue factor-factor VIIa complex and factor Xa to contribute to EC activation by pathologic stimuli. (Modified from Rodgers GM. Hemostatic properties of normal and perturbed vascular cells. *FASEB J* 1988;2:116-123.)

The key hemostatic activity induced by EC perturbants is TF expression, because TF is considered to be the major initiator of coagulation.¹⁴⁶ Details of the regulation of cellular TF activity are given in Chapter 18. Stimuli reported to induce EC TF activity include cytokines, lipopolysaccharide, oxidized LDL, homocysteine, and certain infectious organisms. Expression of EC TF antigen in pathologic human and primate tissues using immunohistochemical methods has been reported,^{147,148} and¹⁴⁹ including vascular tissue from patients with sickle-cell anemia¹⁵⁰ and skin biopsies from patients treated with intradermal cytokines.¹⁵¹ The importance of vessel wall TF activity in arterial and venous thrombosis has been recently confirmed.¹⁵²

EC TF procoagulant activity may be modulated by a novel EC protease, PAR-2. PARs represent a group of G-protein-coupled receptors present in ECs and other tissues.¹⁵³ Thrombin or other proteases cleave the amino terminus of the receptor exodomain; the amino-terminus fragment then binds to the cell-associated domain of the receptor to activate

the protease.¹⁵⁴ In ECs and fibroblasts, activated PAR-1 is internalized and sorted to lysosomes; this process terminates thrombin signaling.¹⁵³

There are at least four members of the PAR family.¹⁵³ Human PAR-1, PAR-3, and PAR-4 can be activated by thrombin, and it is proposed that their *in vivo* role is sensing thrombin generation.¹⁵³ ECs contain both PAR-1 and PAR-2,^{153,155} but thrombin does not activate PAR-2. Rather, data indicate that PAR-2 may be activated directly by TF-factor VIIa and indirectly by TF-factor VIIa-generated factor Xa.¹⁵⁶ It has been proposed that PAR-2 may function as a coagulation protease "sensor" and thereby contribute to EC activation by pathologic stimuli.¹⁵⁶ Stimulation of EC PAR-2 also increases TF expression.¹⁵⁵ EC PAR-2 may mediate additional thrombin-induced vascular functions, including leukocyte adhesion¹⁵⁷ and mitogenesis.^{158,159} Studies investigating embryonic development indicate that PAR-1 messenger RNA is abundant in EC, suggesting that PAR-1 signaling in EC is important in vascular development.¹⁶⁰ PAR-1 also mediates the EC response to APC; APC and ECPCR cleave PAR-1 to initiate signaling events.¹¹¹ Figure 19.6 illustrates the interactions between the TF-factor VIIa complex and EC PAR-2, with resulting alteration of EC function. The role of PARs in vascular biology and disease has been recently reviewed.¹⁶¹

An additional mechanism for EC generation of thrombin has been reported. Perturbed ECs express a prothrombin activator that can generate thrombin independent of the intrinsic and extrinsic coagulation pathways.¹⁶² The description of trypsin expression by

P.505

cultured EC and by vascular EC *in situ* suggests that a variety of EC-derived proteases may also regulate blood coagulation.¹⁶³

FIGURE 19.6. Interactions of the tissue factor (TF)-factor VIIa complex with the endothelial cell protease-activated receptor (PAR)-2 and their consequences. Expression of endothelial cell TF results in TF-dependent factor VIIa activation of PAR-2. Cleavage of the amino terminus of PAR-2 reveals a tethered ligand sequence that binds to PAR-2 to initiate signaling, triggering responses that include calcium influx, expression of surface adhesion molecules for leukocytes, and release of growth factors.^{153,156} Activation of PAR-2 may also enhance endothelial cell expression of TF activity¹⁵⁵ (dashed line).

Because both ECs¹³⁹ and platelets¹⁶⁴ can activate prothrombin, the question arises as to the importance of EC in thrombin generation. One study observed synergism of thrombin generation when a reconstituted model containing ECs, platelets, and purified coagulation proteins was tested.¹⁶⁵ Synergy was maximal at platelet concentrations $<1 \times 10^8$ /ml.¹⁶⁵ Thus, in thrombocytopenic states, the large surface area of vascular endothelium, especially in the microcirculation,⁵⁹ may play a role in amplifying platelet prothrombin activation. Studies with human arterial vascular tissue indicate that vascular tissue alone (in the absence of platelets) is sufficient to generate large amounts of thrombin.¹⁶⁶

Regulation of the anticoagulant protein C pathway by EC perturbants has also been a subject of interest because of the recurrent thrombotic disorders associated with deficiency of protein C pathway components (proteins C and S).^{100,101} Down-regulation of the protein C pathway has focused on thrombomodulin, the EC membrane protein that activates protein C after complexing with thrombin. Several mechanisms have been identified to explain the role of thrombomodulin in down-regulating protein C activation. Thrombomodulin has structural homology to the native LDL

receptor,¹⁶⁷ a prototypical membrane receptor involved in endocytosis. The effects of tumor necrosis factor on the protein C pathway appear to result from enhanced endocytosis and subsequent degradation of thrombomodulin.¹⁶⁸ Additionally, tumor necrosis factor, a cytokine that reduces protein C activation, has been reported to inhibit transcription of thrombomodulin RNA.¹⁶⁹

Another important EC hemostatic property regulated by relevant perturbing stimuli is secretion of PAI-1 and TPA. Treatment of cultured EC with interleukin-1 results in both diminished TPA secretion and increased PAI-1 secretion.¹⁷⁰ Increased amounts of PAI-1 relative to TPA diminish vascular fibrinolytic activity, resulting in enhanced thrombotic potential because of failure to lyse fibrin thrombi.

In addition to the humoral and biochemical stimuli discussed earlier, biomechanical forces (shear stress) can regulate EC gene expression and phenotype.¹⁷¹ For example, either laminar or turbulent shear stress has been reported to regulate a large number of EC genes differentially, including adhesion molecules and growth factors, as well as hemostasis proteins.¹⁷² Shear stress also attenuates cytokine-induced EC TF expression.¹⁷³ These data indicate that vascular endothelium is responsive to biomechanical stimuli. A uniquely flow-induced EC gene is the transcription factor, lung Kruppel-like factor, which may be an important regulator of EC function.¹⁷⁴

Diversity of Endothelial Cell Hemostatic Properties

There is significant heterogeneity in arterial, venous, and capillary EC with regard to expression of hemostatic and other functional activities.^{58,175} For example, aortic EC express more factor V activity than do venous EC,¹³⁰ and PGI₂, a major metabolite secreted by human venous EC, is not substantially produced by human capillary cells.¹⁷⁶ Different fibrinolytic and anticoagulant properties have been reported between cultured venous and capillary EC.¹⁷⁷ Increases in blood flow lead to up-regulation of NO synthase messenger RNA in aortic, but not pulmonary, arterial EC.¹⁷⁸ Vascular anticoagulant activity in the microcirculation is reinforced by geometric aspects of the vessel wall.⁵⁹ For example, the thrombomodulin concentration in the microcirculation would increase more than a thousandfold⁵⁹ compared with a large vessel. Consequently, in large vessels, thrombin circulates freely to catalyze coagulation, whereas in the microcirculation, thrombin exists mostly bound to thrombomodulin, promoting anticoagulation.¹⁰¹

The differential concentration of thrombomodulin in large versus small vessels may also affect vascular fibrinolysis in specific vascular beds. Thrombin-activatable fibrinolysis inhibitor is stimulated by low thrombomodulin concentrations but decreased at high concentrations of thrombomodulin.¹⁷⁹ This implies that enhanced fibrinolysis would be seen in the microcirculation that contains high levels of thrombomodulin activity.

These data suggest a vascular model in which procoagulant activities are dominant in the arterial circulation and anticoagulant activities are dominant in the microcirculation. This distribution of vascular hemostatic properties is consistent with the necessity for rapid thrombin generation and fibrin clot formation after arterial injury, while providing the venous and microcirculation with anticoagulant mechanisms to protect against thrombosis.⁸⁰ Unique EC environments may also explain localization of certain pathologic processes. For example, verotoxin-induced EC platelet thrombi localized to arterioles and capillaries may be explained by distinct responses of EC to verotoxin,¹⁸⁰ and endogenously generated NO is more effective in inhibiting thrombosis in venules than in arterioles.¹⁸¹

The concept of EC diversity is also supported by gene-expression profile studies that have identified characteristic expression patterns of arterial versus venous EC as well as large versus microvascular EC.¹⁸²

INTRODUCTION

This chapter reviews the biochemistry and importance of various blood group antigens with a focus on red cells, platelets, and white blood cells. Because the circulating blood cells originate from a common progenitor cell, it is not surprising that there are a number of common blood group antigens. But what is surprising is the fact that the various cell lineages have so many unique and different antigens.

Studies characterizing the red cell antigens were first performed approximately 100 years ago, whereas studies investigating the platelet and white cell antigens were performed much more recently. There are a number of explanations for this, including the earlier recognition of red cells and the early attempts to transfuse these cells. Additionally, red cells have proved to be not only more plentiful, but also easier for investigators to work with. Indeed, the early techniques used to study red cell antigens, such as primary and secondary agglutination reactions using direct and indirect antiglobulin tests, proved so robust that they are still used today.

The nomenclature used for red cells is complex, yet historically interesting. Until recently, there was no attempt to be systematic. In the past, some blood groups were named after the individual (Kell is derived from Mrs. Kellner) or animal (Rh is derived from the rhesus monkey) lacking the antigen. Others were named after the discoverers (e.g., LW was named for Landsteiner and Weiner). Finally, some names are best described as quaint (e.g., the Lutheran blood group system was named according to a mislabeled blood sample). As is discussed, a more systematic approach for naming antigenic systems of red cells, platelets, and white cells is now used. However, the traditional names are still frequently used and, to add to the confusion, a number of laboratories continue to use other traditional nomenclatures (e.g., the Fisher-Race terminology continues to be used for the Rh system).

For biologists, a compelling question presents itself: What are the purposes of blood group antigens? For the majority of antigens, the answer is unknown, but there is increasing evidence that suggests certain antigens participate in host defense. Blood group antigens of red cells, platelets, and white cells can be made of proteins, carbohydrates attached to proteins, or lipids. Within each category, the antigen can be intrinsically produced during the formation of that cell, or it can be adsorbed from the plasma. Similarly, the antigens can be attached to the surface of the cell, can be partially embedded within the membrane (phosphatidylinositol glycan), or can be transmembrane. Recognizing this, investigators have grouped red cell antigens according to the functional activities of their associated carbohydrate, lipid, or protein.^{1,2} These include functions such as membrane stabilization, transport across the membrane, receptor function, enzymatic activity, and others. However, it is important to emphasize that although these blood group antigens are one component of this particular function, there is little evidence that they exist solely for this function. Consequently, although it is interesting to understand how a protein or carbohydrate associated with a blood group antigen contributes to a cell's integrity, it may not be the sole explanation for the presence of the antigen.

Any discussion of blood group antigens must touch on disease associations. In this review, we also comment on generally agreed on associations. Readers should be cautious about the reported associations between certain blood groups and diseases, as these associations could be collateral to other factors. However, there is general agreement that infectious agents, especially parasites and some bacteria, have led to blood group antigenic selection. Perhaps this is best exemplified by the geographic distribution of the Duffy blood group system, which is encoded by two alleles. The Fy(a-b-) phenotype is rare in most populations, with the exception being blacks originating from West Africa. Studies have demonstrated that the Duffy glycoprotein can serve as a receptor for *Plasmodium vivax*, an etiologic agent of malaria; hence, there is a strong selection advantage for those individuals not expressing this glycoprotein (i.e., Fy [a-b-]).

These dramatic observations and other studies provide indirect evidence that perhaps the major biologic advantage of antigens on cells is to enhance the ability of the species to distinguish self from non-self. Hence, one can anticipate in the ongoing "evolutionary warfare" between species and their invaders that when a microorganism uses a component of a blood group to invade that cell, spontaneous mutations producing another blood group would have a selective advantage. Additionally, nonhazardous mutations, which do not provide advantage or disadvantage, might not necessarily be deleted. It is likely that this helps to explain the enormous number of blood groups found on red cells, platelets, and white cells. Some of these blood groups are common (typically termed public systems within the platelet nomenclature), whereas others are rare (termed private systems).

This chapter summarizes red cell and platelet blood groups by first summarizing the approach to nomenclature and then reviewing the common blood groups.

P.510

RED BLOOD CELL ANTIGENS

In humans, 33 blood group systems with 298 antigens have been identified.^{3,4,5} Additional antigens have been identified but have not been assigned to established systems. Red blood cell antigens may be proteins, glycoproteins, or glycolipids. Most red cell antigens are synthesized by the red cells; however, some antigens, such as those of the Lewis and Chido/Rodgers systems, are adsorbed onto the red cell membrane from the plasma. Some red cell antigens are specific to red cells; however, others are found on other cells throughout the body.

The importance of red cell antigens is multifold. Since the work of Landsteiner in the early 1900s, it has been recognized that knowledge and understanding of blood groups are essential for transfusion therapy. In routine practice, it is necessary to determine the compatibility of certain red blood cell antigens between the blood donor and the blood recipient. This is because individuals who lack antigens on their red blood cells can form alloantibodies, or be alloimmunized, if they are exposed to blood expressing the antigen. This might occur with transfusion of blood products or during pregnancy. Antibodies that react with red blood cell antigens can cause problems such as delayed and immediate hemolytic transfusion reactions (HTRs) and hemolytic disease of the newborn (HDN). Furthermore, the study of red cell antigens and the associated membrane structures allows for a greater understanding of the physiology of red blood cells. For example, abnormalities of some blood group systems, such as Rh and Kell, may be associated with both functional and morphologic changes in the red cells. Finally, study of the inheritance of blood group antigens provides a greater understanding of the mechanisms of gene expression.

In this chapter, the red cell antigen groups are presented in order of relative clinical importance. The summary tables, given in each antigen section, list important clinical information and the most important antigens of each blood group

system. As noted, many red cell antigens (as well as the platelet antigens) have an interesting but inconsistent approach to nomenclature. However, because these names are commonly used, they are used along with the nomenclature proposed by the International Society of Blood Transfusion (ISBT).

International Society of Blood Transfusion Terminology

The ISBT Working Party on Terminology for Red Cell Surface Antigens was established in 1980 with the goal of creating a uniform nomenclature. Blood antigens were categorized into systems, collections, and series. The most recent monograph produced by the Working Party was produced in 2004 and included blood group antigens categorized into 29 systems, six collections, and two series.⁶ Updates to this monograph have been published online (<http://ibgri.blood.co.uk/ibgri/ISBT%20Pages/ISBT%20terminology%20pages/terminology%20Home%20page.htm#system>) and there are now 30 systems recognized.

Systems

A blood group system is genetically discrete from other blood group systems and consists of one or more antigens governed by either a single gene locus or a complex of two or more closely linked genes with virtually no recombination events occurring among them. Furthermore, it must be defined by a human alloantibody, and the gene encoding it must have been identified and sequenced. There are currently 30 recognized systems (Table 20.1).

Collections

The concept of collections was introduced into the ISBT terminology in 1988 to bring together related sets of antigens (genetically, biochemically, or serologically), which could not correctly be classified as systems because they have not been shown to be genetically distinct from all existing systems. Seven collections are currently recognized (Table 20.2).

Series

An antigen may be assigned a number if it is a low-frequency antigen (the 700 series) or if it is a high-frequency antigen (the 901 series). A low-frequency antigen is an antigen that has an incidence of <1% in most populations tested, similar to the platelet designation of "private." The 700 series currently consists of 18 antigens (Table 20.3). High-frequency antigens are antigens with an incidence of >90% in most populations, similar to the platelet "public" system. Originally, high-frequency antigens were assigned to the 900 series. However, because so many of the original antigens assigned to the 900 series have been reassigned to collections, the 901 series was created. There are currently six antigens in the 901 series (Table 20.4).

Each blood group antigen is given an identification number consisting of six digits. The first three numbers represent the system to which the antigen has been assigned. The second three digits identify the antigen. Each system also has an alphabetic symbol. For example, the ABO system is number 001, and the A antigen is the first antigen of that system; thus, it has the ISBT number 001001 or ABO001. By convention, the zeros may be omitted, and numbers are separated by a dot (i.e., the A antigen would be 1.1 or ABO1). This terminology is useful for databases and as a classification system; however, most clinical laboratories still use traditional terminology.

Red Cell Blood Group Systems

ABO (ISBT 001) and Hh (ISBT 018) Blood Group Systems

SUMMARY OF IMPORTANT CHARACTERISTICS OF ABO ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
Anti-A	Yes	IgM; some IgG	Yes	Yes	Common (53%)
Anti-B	Yes	IgM; some IgG	Yes	Yes	Common (87%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The ABO blood group system was discovered by Landsteiner in 1900 when he noticed that the red cells of some individuals could be agglutinated by the serum of others. It remains the most important of all blood group systems for several reasons: (a) when the ABO antigen is not expressed on the red cell, individuals always have ABO antibodies in their plasma, with the stimulus for antibody production being a variety of environmental agents; and (b) the ABO antibodies

formed are frequently mixtures of both immunoglobulin M (IgM) and IgG antibodies, both having thermal reactivity at 37°C and both capable of activating complement.

These unique characteristics of the antigens and antibodies of the ABO blood group system provide optimal conditions for rapid

There are three alleles of the ABO gene in the ABO blood group system (A, B, and O) that are inherited in Mendelian fashion (Table 20.1). Both A and B are codominant alleles, whereas O is a recessive allele. Hence, these three result in four different phenotypes: A, B, AB, and O. An individual with the A phenotype can be homozygous for the A gene (AA) or heterozygous (AO). Similarly, the B phenotype can be the result of homozygous (BB) or heterozygous (BO) gene inheritance. The genotype of the AB phenotype is AB, and the group O phenotype is always genetically OO. Thus, there are four ABO group phenotypes (A, B, AB, and O) that arise from six possible genotypes (AA, AO, BB, BO, AB, and OO). The alleles normally occupy the same position of a paired chromosome. Rarely, individuals may express a cisAB phenotype in which the A and B alleles appear to be carried on the same chromosome. This phenomenon is caused by a collection of mutant ABO alleles that encode a glycosyltransferase capable of synthesizing both A and B antigens.⁷

The frequencies of ABO phenotypes are variable among different ethnic populations. In whites, the O and A phenotypes are the most common, occurring in >40% of the population. The B phenotype is found in approximately 10% of whites, and the AB phenotype is encountered in only 3% of individuals. In contrast, around the world, the O phenotype is the most common ABO phenotype, particularly in South and Central America. The A phenotype is found in 10 to 35% of individuals throughout the world with the highest frequency among the aborigines of northern Scandinavia and northern America.

ABO Gene

The ABO gene is located at 9q34.2. The gene consists of at least seven exons spanning over 18 kb in the DNA genome. The A and B alleles result from differences in seven nucleotides, resulting in different substrate specificity of the encoded enzyme. The difference in substrate specificity is mainly determined by the amino acids 266 and 268 in exon 7.⁸ The O phenotype is due to either a frameshift mutation leading to a stop codon or, rarely, a mutation producing a nonfunctional enzyme. Numerous mutations are found in ABO, but the most common mutation results in the A₂ phenotype. In A₂, the A allele of the ABO gene has two nucleotides different from the A₁ phenotype, which results in diminished enzymatic activity and, consequently, weakened antigen expression. For example, a red cell with A₁ phenotype carries more than 800,000 A antigens, but only 250,000 A antigens are present in a red cell with the phenotype A₂.⁹ Similarly, weak subgroups of group B have been described due to mutations of the B allele of the ABO gene.

ABO Antigens

The antigens of the ABO system are located on carbohydrate oligosaccharide chains, which are parts of glycosphingolipids or gp molecules. There are four different types of oligosaccharide chains: Type 2 and type 4 oligosaccharide chains are predominantly on the red cell membrane; type 1 chains are found in plasma, saliva, and body fluids; and type 3 chains are found in the mucins secreted by gastric mucosa or ovarian cysts.

The ABO gene does not encode directly for the antigens but encodes for enzymes that add specific sugars to the red cell membrane. These sugars are the ABO red cell antigens that are detectable with serologic testing. The A allele encodes for the $\alpha(1,3)$ N-acetyl-galactosaminyl-transferase which adds an N-acetylgalactosamine to the red cell membrane. The B allele encodes for the $\alpha(1,3)$ galactosyltransferase which adds a galactose to the red cell membrane. In an individual with the AB phenotype, the A and B transferases coexist and compete for the same substrate. The O

P.513

allele encodes for a nonfunctional transferase; hence, a specific sugar is not attached to the red cell membrane. Mutations of the A and B alleles result in amino acid substitutions within the transferases, and this translates into weakened expression of the A and B antigens (frequently classified as subgroups). The most common subgroups associated with the A allele are A₁ and A₂. The A₁ subgroup occurs in approximately 80% of group A individuals, and the A₂ subgroup is present in approximately 20%. The other subgroups of A are less frequently encountered, with the A₃ subgroup being the next most frequent, occurring in 1 in 1,000 individuals. The clinical relevance of A and B subgroups is of greater significance in blood donors than recipients. Because of the weakened antigen expression on the red cells of an individual who has inherited a subgroup allele, it is possible that serologic phenotyping of red cells results in misclassification of the red cell phenotype as group O. For a blood recipient, this would not be a problem, as group O blood is compatible with all other

groups (universal donor); however, if a donor unit of blood from an individual with an A or B subgroup is misclassified as group O and transfused to an O individual, intravascular hemolysis could result.

On the red cell membrane, both the A and B transferases add sugar moieties to a substrate that is encoded by the H (FUT1) gene. FUT1 is located at chromosome 19q13.1-qter, and the genes inherited at this locus are inherited in a Mendelian manner. Two alleles have been identified at this locus: H and h. The allele H, most frequently inherited, encodes for an enzyme termed H transferase type II [$\alpha(1,2)$ fucosyl-transferases; FUT1], which adds an L-fucose to the terminal galactose molecule of oligosaccharide chains in an $\alpha(1-2)$ linkage. This structure is called H substance, and it is to this structure that the A and B transferases add specific sugars resulting in A and B antigens. The rare allele sometimes inherited at the H locus is h. This h allele encodes for a nonfunctional transferase. If the h allele is inherited in the homozygous state (hh), L-fucose molecules (H substance) are not present on the red cell membrane. Without the presence of H substance on the red cell membrane, the A and B transferases, even when present, are not able to add the specific sugars that give A and B antigen specificity. This hh genotype is known as the Bombay phenotype: Serologically, the red cells group as O; however, unlike the true O phenotype, which has large amounts of H antigen on the red cells, red cells from the Bombay phenotype lack H antigen (Fig. 20.1). Children of a parent with the Bombay phenotype (hh) may have normal A or B antigen expression, or both, if they inherit

the dominant H allele from the other parent. The clinical relevance of the Bombay phenotype relates to the ability of these individuals to form not only anti-A and anti-B but also anti-H. The presence of all three of these antibodies makes it difficult to find compatible blood if transfusion is required. The only compatible blood for an individual with the Bombay (hh) phenotype is blood from another Bombay individual, and this phenotype is extremely rare.

FIGURE 20.1 Biosynthesis of ABO blood group antigens. The antigens of the ABO system are located on the carbohydrate of type II oligosaccharides. H transferase is required to add fucose to the oligosaccharide chain and form H substance. Without the presence of H substance, A transferase and B transferase are not able to add terminal sugar moieties to the oligosaccharide chain. Fuc, l-fucose; Gal, d-galactose; Glc-NAc, d-N-acetyl-glucosamine.

The ABO(H) antigens are found not only on red cells, but also on other blood cells; in most body fluids (except cerebrospinal fluid); and on the cell membranes of tissues such as intestine, urothelium, and vascular endothelium. The expression of ABO(H) antigens on the red cell membrane and tissue membranes is controlled by the FUT1 (H) gene. The expression of ABO(H) antigens into body fluids is controlled by the FUT2 (Se) gene. The FUT2 gene, similar to the FUT1 (H) gene, is located at chromosome 19 (19cen-qter); however, they are not part of the ABO system. The dominant Se allele codes for H transferase type 1 [$\alpha(1,2)$ fucosyltransferase; FUT2]. Without the prior addition of a fucose to the oligosaccharide chains, A and B antigens would not be expressed in the body secretions, irrespective of the presence of A and B transferases (Fig. 20.1).

Despite the wide distribution of ABO(H) antigens in various cell membranes and body fluids, the normal physiologic function of these glycoproteins and glycolipids is largely unclear. The carbohydrate moieties of the ABO(H) antigens might contribute to the formation of glycocalyx. However, based on the observation that individuals who lack all ABH antigens (Bombay phenotype) have normal red cell survival and function, the role of ABO antigens in maintaining a state of health is unknown.¹⁰ There is some evidence that ABO blood groups may be associated with certain diseases.¹¹ For example, the normal range of von Willebrand factor (vWF) antigen level varies among individuals with different ABO blood groups. Individuals with blood group O have the lowest vWF antigen level, followed by group A, then group B, and the highest levels in those with group AB.¹² However,

P.515

the normal range of vWF is generally defined as the level in the normal general population irrespective of the ABO blood group. It has been postulated that ABO antigen expression can affect the glycosylation, thus altering the proteolysis and clearance of vWF.^{13,14} Studies have shown that individuals with blood group O are less susceptible to arterial and venous thromboembolism possibly associated with a lower level of vWF.^{14,15} and ¹⁶ In addition, blood group ABO may be associated with resistance to certain infections and, therefore, may offer a survival advantage. For example, individuals with blood group O may be less susceptible to severe Plasmodium falciparum malaria,^{17,18} but may be more likely to have severe infection with Vibria cholerae O139^{19,20} or Escherichia coli O139.²¹ Gastric cancer and peptic ulcer disease have been reported to be more prevalent in individuals with blood group O^{22,23} because of the association between blood group O and a gastric pathogen, Helicobacter pylori. It has been shown that H. pylori binds more readily to gastric epithelium in group O individuals because of lack of expression of ABO and Lewis antigens in non-hematopoietic tissue (see also section on Lewis antigens).²⁴ In contrast, secretors of ABO and Lewis antigens in the gastrointestinal tract are more susceptible to norovirus,²⁵ rhinoviruses, echoviruses, influenza viruses, and respiratory syncytial virus.²⁶

Antibodies and Clinical Significance

All immunocompetent individuals produce antibodies against the missing ABO(H) blood group antigens (Table 20.5). Anti-A and anti-B production does not require red cell stimulation through transfusion or pregnancy but occurs predominately through environmental exposure, such as bacteria.²⁷ Anti-A and anti-B are usually detectable within 3 to 6 months after birth.²⁸ By the age of 5 years, the titers of anti-A and anti-B antibodies reach maximum and persist throughout adulthood. The titers of IgM anti-A and anti-B antibodies may gradually decline with advanced age.²⁹ Newborn infants do not usually have a significant amount of anti-A or anti-B in their plasma; therefore, pretransfusion testing is not usually required for transfusions within the first 4 months of life. Infants born to alloimmunized mothers are an exception to this rule, as other specific blood group antibodies may have crossed the placenta and may be present in the infant's circulation.

The “naturally occurring” anti-A and anti-B antibodies are predominantly IgM, although variable amounts of IgG may be present. Like most IgM immunoglobulins, ABO antibodies are especially effective at complement activation for two reasons: the antibodies have thermal activity most reactive at body temperature, and the high density of antigen sites on the red cell membrane allows for large numbers of antibodies to bind to the cell membrane. Therefore, the transfusion of ABO-incompatible blood typically presents as acute intravascular hemolysis. Anti-ABO antibodies, anti-human leukocyte antigen (HLA) antibodies, and anti-human platelet antigen (HPA) antibodies can cause alloimmunization resulting in platelet transfusion refractoriness.³⁰ The ABH expression on the platelet is linked to the red cell phenotype; yet the expression on the platelet may be determined mainly by the enzyme H transferase type II (FUT1).³¹

TABLE 20.5 SUMMARY OF ABO GENES AND ANTIGENS

Phenotype	Antibody	Antigen	Gene Product	Gene
A	Anti-B	N-acetylgalactosamine	A transferase	9q34.1-q34.2

B	Anti-A	D-galactose	B transferase	9q34.1-q34.2
AB	None	<i>N</i> -acetylgalactosamine and D-galactose	A transferase and B transferase	9q34.1-q34.2
O	Anti-A and anti-B	L-fucose	Absent or nonfunctional A or B transferase	Absent or nonfunctional gene
A ₂	Anti-B and variable amount of anti-A ₁	<i>N</i> -acetylgalactosamine	A transferase	9q34.1-q34.2

In allogeneic stem cell transplant, ABO incompatibility may cause hemolysis, pure red cell aplasia, and delayed engraftment of donor cells.³² However, ABO incompatibility may not affect the long-term survival.^{32,33} After ABO unmatched hematopoietic stem cell transplantation, the patient's red cells will switch to the donor's blood group. Due to the fact that ABO antigens are not limited to the red cells, peripheral tissue may continue to express the recipient's original antigens for life.³⁴ These isohemagglutinin will be adsorbed onto the red cells and cause ABO discrepancy during crossmatch.^{35,36} Similarly, in kidney transplantation, ABO-incompatible recipients have higher graft loss in the immediate posttransplant period, but the long-term survival is similar to those with ABO-mismatched recipients.³⁷ Moreover, delay in the production of ABO antibodies in infants may provide an "immunologic gap" for ABO-incompatible organ transplantation.³⁸

The antibodies against ABO antigens are not a major cause of HDN for several reasons. First, soluble A or B substance in the fetal plasma can neutralize the alloantibodies. Second, antigens A or B expressed on other body tissues may also bind alloantibodies. Third, alloantibodies against ABO antigens are specific for sugar molecules; these antibodies generally have a weaker binding affinity than anti-bodies reacting with protein antigens such as the D antigen.

In routine blood group typing, the transfusion recipient's red cells are typed using commercial sources of anti-A and anti-B antibodies (forward or cell typing). The presence of anti-A and anti-B in the serum/plasma of the recipient is detected by testing the serum/plasma against group A and group B red cells (reverse or serum typing). The interpretation of these two tests must agree for the patient's blood group to be assigned. Sometimes, the serum and cell grouping do not agree; this is termed ABO discrepancy. In these circumstances, the laboratory should proceed with additional testing to correctly identify the patient's ABO blood group. New technologies in blood group genotyping may identify and resolve these discrepancies.

Discrepancies in ABO grouping can be found in various conditions. For example, the ABO(H) antigens may be weakened in the donors with mutations of the ABO alleles. In patients with some types of leukemia or cancer, or having diseases associated with chromosome 9 translocations, the ABO(H) antigens may also be weakened and serologically typed as negative for that particular antigen. Alternatively, an individual may acquire an ABO antigen on the red cells; for example, one can acquire a B antigen after bacterial infections, or acquire an A antigen associated with Tn activation of the red cells.³⁹

P.516

Rh Blood Group System (ISBT 004)

SUMMARY OF IMPORTANT CHARACTERISTICS OF RH ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
Anti-D	Yes	IgG; some IgM	Yes	Yes	Common (15%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Rh blood group system was discovered by Landsteiner and Weiner in 1940.⁴⁰ They injected rabbits with red cells from the rhesus monkey, and the antibody produced was initially termed Rh and is now known as anti-D. Unlike the ABO blood group system, Rh antibodies are not environmentally stimulated; however, the D antigen is highly immunogenic, causing anti-D formation in up to 70% of D-negative individuals who are exposed to D-positive blood. Anti-D is IgG and is known to cause HTRs and HDN.

Rh Terminology

Three different systems of nomenclature have been developed to describe the genes and antigens of the Rh blood group system antigens: The Wiener system, the Fisher-Race system, and the Rosenfield numeric terminology. Wiener proposed that the Rh antigens were the products of a single gene.⁴¹ The Fisher-Race nomenclature was based on the theory that reactions observed with various Rh antisera could be explained by three pairs of allelic genes: Cc, Dd, and Ee.⁴² Genetic analysis does not support either of these models. However, both the Wiener notation and the Fisher-Race nomenclature remain widely used today because of familiarity. In 1962, Rosenfield et al. proposed a system of nomenclature that was based on serologic findings.⁴³ The symbols were used to convey phenotypic information rather than genetic information.⁴⁴ In this system, the antigens are numerically named in order of their discovery or assignment to the Rh blood group system. The various nomenclatures for common Rh system antigens are listed in Table 20.6.

TABLE 20.6 RH BLOOD GROUP SYSTEM: ANTIGENS

Rh9	C ^x	rh ^x
Rh10	V (Ce ^s)	hr ^v
Rh11	E ^w	rh ^{w2}
Rh12	G	rh ^G

Genes

The Rh antigens are encoded by two genes: RHD and RHCE. The genes are located at chromosome 1p36.11 (Table 20.1). RHD encodes for the D antigen, whereas RHCE encodes for the Cc and Ee antigens. The d antigen does not exist; however, by convention, d is used to connote the absence of the D antigen. RHD and RHCE each contain ten exons and are distributed over 69 kilobase pairs (kbp).⁴⁵ Both the RHD and the RHCE genes encode for similar polypeptides of 417 amino acids with 12 membrane-spanning domains.⁴⁵ In the red cell membrane, these two polypeptides form a complex with a glycoprotein termed the Rh-associated glycoprotein (RhAG), which is encoded by the RHAG gene (RH50) on chromosome 6. The RhAg and associated antigens have recently been designated the thirtieth blood group system. The structure of the Rh antigens suggests that they are transport proteins and the RhAG protein may play a role in the transport of ammonium. The Rh-associated proteins are transport proteins involved in ammonia/ammonium transport.^{46,47} The physiologic role of the Rh protein is poorly defined, but it has been suggested that these proteins may act to keep total blood ammonia low by trapping ammonium within the red blood cell.^{46,48}

Antigens

There are 54 antigens that have been assigned to the Rh blood group system: D, C, E, c, e, f, Ce, C^w, C^x, V, E^w, G, Hr_o, Hr, hr^s, VS, C^G, CE, D^w, c-like, cE, hr^H, Rh29, Go^a, hr^B, Rh32, Rh33, Hr^B, Rh35, Be^a, Evans, Rh39, Tar, Rh41, Rh42, Crawford, Nou, Riv, Sec, Dav, JAL, STEM, FPTT, MAR, BARC, JAHK, DAK, LOCR, CENR, CEST, CELO, CEAG, PARG, and CEVF (Table 20.1). Of the 54 antigens in the Rh blood group system, the most common and important are D, C, E, c, and e. Although individuals can become alloimmunized to the C, c, E, and e antigens after red cell exposure through transfusion or pregnancy, these antigens are much less immunogenic than D. Less than 3% of individuals exposed to the C, c, E, and e antigens become alloimmunized; hence, pretransfusion testing is not routinely performed to match for these antigens. The principal phenotypes of the Rh blood group system and their frequencies are outlined in Table 20.7.

An individual is considered to be Rh positive if his or her red cells express the D antigen. The term Rh negative refers to the absence of the D antigen. The absence of the D antigen occurs in approximately 15% to 17% of individuals in white populations and is less frequent in other populations.⁴⁹ In white populations, the absence of the D antigen is usually due to the deletion of the RHD gene.⁴⁹ In Asian and black populations, the absence of the D antigen is usually due to an inactive RHD rather than a gene deletion.^{50,51}

TABLE 20.7 RH BLOOD GROUP SYSTEM: PRINCIPAL PHENOTYPES

Fisher-Race	Wiener	Frequency (%)		
		Whites	Blacks	Asians

P.517

Cis Product Antigens. Ce(rh₁) is an antigen that almost always accompanies C and e when they are encoded by the same haplotype.⁴⁴

Cc and Ee Variant Antigens. Various Rh antigens appear to be determined by alleles of the Cc and Ee antigens. Variants of C include C^w(Rh8), C^x(Rh9), and MAR. Variants of the E antigen include E^w(Rh11) and E^T(Rh24). Variants of the e antigen include hr^B (Rh31), hr^s (Rh19), and e^s(Rh20).

G Antigen (Rh12). The G antigen is found on any red cell that also has the C or D antigen.

Weak D Phenotype

Some red cells that express the D antigen require prolonged incubation with the anti-D reagent or application of the antiglobulin test for agglutination to occur. These red cells are considered to be D antigen-positive and are described as weak D, formerly termed D^u. The weak D phenotype is thought to occur by one of three mechanisms: (a) inheritance of an RHD gene encoding for a weakened expression of D, (b) interaction of the D allele with other genes, and (c) inheritance of an RHD gene missing some epitopes. In the first mechanism, the weak D phenotype is due to an RHD gene encoding for a D protein with reduced D antigen expression.⁴⁴ This is more common in the black population and generally occurs in association with the Dce haplotype. In the white population, weak D is less common but may occur in association with the haplotype DCe or DcE.⁴⁴ In the second mechanism, the weak D phenotype occurs as a result of the position of the D allele. This is most easily conceptualized using the Fisher-Race terminology. Red cells from individuals with a C allele in a trans position to the D allele (i.e., Dce/Ce) have weakened expression of D due to C being on the opposite chromosome. Individuals with the weak D phenotype by either of these two mechanisms do not form alloantibodies after exposure to D-positive red cells. Finally, the third mechanism, sometimes termed partial D, occurs when individuals lack part of the D antigen complex. The D antigen is thought to be a mosaic consisting of several individual parts or epitopes. Most D-positive individuals inherit the gene encoding the entire D antigen. However, the partial D phenotype describes red cells that are deficient in components of D, resulting in a decreased expression of the D antigen (weak D). Individuals with partial D may produce anti-D if transfused with D-positive red cells.

The weak D and partial D phenotypes have implications for the practice of transfusion medicine. Donors with weak D red cells should be considered Rh(D) positive. It is important that donor blood with weak D not be mislabeled as Rh(D) negative because the weak D antigen could induce an immune response if this blood were transfused to an Rh(D)-negative individual.³³ It is generally recommended that patients who phenotype as weak D can be transfused with Rh(D)-positive

blood. The most common types of weak D do not appear to be at risk of alloimmunization to the D antigen, therefore, these individuals can safely receive D-positive blood and would not require Rh immune globulin prophylaxis during pregnancy. However, it should be noted that some weak D types, identified by molecular analysis or the RHD gene are susceptible to alloimmunization.⁵²

Rh_{null} Phenotype

The Rh_{null} phenotype occurs when red cells do not express Rh antigens. This phenotype occurs because of at least two mechanisms. First, the inheritance of an abnormal RHAG gene appears to result in the absence of the Rh antigen expression despite the presence of normal RHD and RHCE genes.³⁰ This is termed regulator type Rh_{null}. The second mechanism is termed amorph type of Rh_{null} and involves the inheritance of a mutation in the RHCE genes in association with a D-negative background.⁵³ The Rh_{null} phenotype is associated with abnormalities in the red cell membrane causing stomatocytosis and hemolysis. The presence of the Rh proteins in the red cell membrane appears to be necessary for the expression of other membrane proteins such as the LW, Duffy, and U antigens. Rh_{null} cells have been demonstrated to lack the LW and Fy5 antigens and have weakened expression of the S, s, and U antigens.⁵⁴ Fortunately, the Rh_{null} phenotype is rare, as these individuals form an alloantibody (anti-Rh29) that reacts with all other red cells except Rh_{null} when they are transfused. Thus, obtaining compatible blood can be challenging.

Antibodies and Clinical Significance

Most Rh antibodies are IgG, although some may be IgM. They are usually not capable of activating complement. Anti-D is one of the most common Rh antibodies because of the high immunogenicity of the D antigen. Anti-D can cause severe HDN and HTR. The frequency of anti-D has greatly decreased with the use of prophylactic Rh immune globulin administration to Rh(D)-negative mothers during pregnancy and at delivery if the infant is Rh(D) positive. Antibodies against antigens of the Rh system including C, c, E, and e can be associated with mild HTR or HDN.⁴⁹

Kell Blood Group System (ISBT 006)

SUMMARY OF IMPORTANT CHARACTERISTICS OF KELL ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
Anti-K	Yes	IgG; rarely IgM	Yes	Yes	Very common (98%)
Anti-k	Yes	IgG; rarely IgM	Yes	Yes	Rare (<2%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Kell blood group system was discovered in 1946 and was named after Mrs. Kellner, the mother of the first child discovered to be affected with HDN because of Kell antibodies.^{55,56}

Genes and Antigens

The Kell blood group system consists of 35 antigens: K, k, Kp^a, Kp^b, Ku, Js^a, Js^b, Ul^a, K11, K12, K13, K14, K16, K17, K18, K19, Km, Kp^c, K22, K23, K24, VLAN, TOU, RAZ, VONG, KALT, KTIM, KYO, KUCI, KANT, KASH, KELP, KETI, KHUL, and KYOR. The antigens are coded by a complex of genetic loci, known as the Kell locus, which is located at 7q33 (Table 20.1). The KEL gene contains 19 exons distributed over 21.5 kbp.⁴⁵ There are at least four subloci in the complex, each of which has an allele for a high-frequency antigen (k, Kp^b, Js^b, and KEL11) and for one or more alleles for a lower-frequency antigen (K, Kp^a and Kp^c, Js^a, and KEL17).⁵⁷ The most common haplotype is k/Kp^b/Js^b/Kel11. The phenotype frequency of the common Kell antigens is shown in Table 20.8. The k antigen is a high-frequency antigen that is present in more than 98% of whites and blacks. The K antigen is much less common.

The KEL gene encodes a type 2 integral membrane protein, called zinc endopeptidase, containing 732 amino acids, which is present at 3,500 to 17,000 copies per red blood cell.^{45,56} The protein has enzymatic activity, and it has been demonstrated in vitro to cleave big endothelin-3, which is a peptide with vasoconstrictor activity.⁵⁸ The Kell protein is associated with the Kx protein in the red cell membrane (see section Kx Blood Group System [ISBT 019]).⁵⁹ Individuals have been identified who do not express the Kell protein (Kell_{null} phenotype) and who are healthy with no structural or functional abnormalities of their red cells identified.

TABLE 20.8 PRINCIPAL PHENOTYPES OF BLOOD SYSTEMS

P.519

Antibodies and Clinical Significance

The K antigen is very immunogenic. Only the D antigen has greater potential to induce alloimmunization. Because of this, anti-K is often encountered. Anti-K typically is induced by blood transfusion. The antibody tends to be IgG. Anti-K is

clinically significant and has been implicated in both HTR and HDN. There is poor correlation with maternal anti-K titer and disease severity.⁶⁰ Furthermore, HDN associated with anti-K tends to be more severe than HDN caused by anti-D. This is thought to occur because the Kell antigens are well expressed on fetal cells and appear on erythroid progenitor cells. It is postulated that anti-K, in addition to causing hemolysis, also causes a suppression of erythropoiesis.^{61,62}

The k antigen is also highly immunogenic. However, because only individuals not expressing the k antigen (i.e., KK phenotype) produce anti-k, and because the k antigen is present in most individuals, anti-k is much less common. Anti-k has been associated with both HDN and HTR. The other Kell blood group system antibodies are much less common but are also clinically significant.

Duffy Blood Group System (ISBT 008)

SUMMARY OF IMPORTANT CHARACTERISTICS OF DUFFY ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
Fy ^a	Yes	IgG	Yes	Yes	Common (34%)
Fy ^b	Yes	IgG	Yes	Yes	Common (17%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Duffy blood group system was discovered in 1950 in the serum of a multiply transfused male patient with hemophilia, Mr. Duffy.⁶³

Gene and Antigens

The Duffy system consists of six antigens, Fy^a, Fy^b, Fy³, Fy⁴, Fy⁵, and Fy⁶, which are encoded at the Duffy locus on chromosome 1q21-q22 (Table 20.1). The gene, DARC (or FY), contains two exons distributed over 1.521 kbp.⁴⁵ The antigens, Fy^a and Fy^b, are encoded by a pair of codominant alleles. The phenotypes of the Duffy system and their frequencies are presented in Table 20.8. The most common phenotype in the white population is Fy(a+b+), and the most common phenotype in the black population is Fy(a-b-). The Fy^x antigen represents a form of weak Fy^b. The Fy⁵ antigen is defined by an interaction of the Duffy and Rh gene products.⁴⁴ The antigens Fy^a, Fy^b, and Fy⁶ are sensitive to denaturation by enzymes such as papain, ficin, or α-chymotrypsin. Fy³ and Fy⁵ are not sensitive to enzyme denaturation.

The Duffy DARC gene encodes for a glycoprotein (DARC) that is found on red cells as well as other tissues including brain, heart, lung, kidney, and spleen. On red cells, the glycoprotein has been identified as a receptor for various chemokines and may contribute to chemokine-induced leukocyte migration to sites of inflammation.^{64,65} DARC may also play a role in renal disease as increased DARC expression has been noted in different causes of renal injury.⁶⁶ It is thought that DARC expression is increased in an attempt to control inflammation.⁶⁶ The glycoprotein is also the receptor for *P. vivax* and *P. knowlesi*. Therefore, individuals who do not express Fy^a or Fy^b on their red cells are not susceptible to these forms of malaria. In parts of Africa where malarial infection is common, most individuals are Fy(a-b-), likely because of natural selection.⁴⁴

Antibodies and Clinical Significance

The Duffy antibodies are usually IgG. Anti-Fy^a is a common alloantigen. Fy^a is considered clinically significant, as it has been associated with HDN and HTR. Anti-Fy^b is uncommon. It has been associated with mild HTR and only rarely with HDN.^{44,67} The other Duffy antibodies are much less common.

Kidd Blood Group System (ISBT 009)

SUMMARY OF IMPORTANT CHARACTERISTICS OF KIDD ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
Jk ^a	Yes	IgG; rarely IgM	Yes	Yes	Common (23%)
Jk ^b	Yes	IgG; rarely IgM	Yes	Yes	Common (28%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Kidd blood group system consists of three antigens: Jk^a, Jk^b, and JK3 (Table 20.1). The system was named for the woman (Mrs. Kidd) whose serum was found to contain the antibody, and the antigen was named Jk for the initials of the woman's child (John Kidd) affected by HDN.⁶⁸

Gene and Antigens

The Kidd blood group system gene is located at chromosome 18q11-q12. The gene, SLC14A1, also known as JK or HUT11, is distributed over 30 kbp and contains 11 exons.⁴⁵ It encodes for the urea transporter hUT-B1.⁶⁹ The principal phenotypes of the Kidd blood group system and their frequencies are outlined in Table 20.8. The antigens Jk^a and Jk^b are found at relatively the same frequencies in the white populations but differ in other ethnic groups such as blacks and Asians.⁴⁵ The Jk(a-b-) phenotype is rare and is found primarily in the Polynesian population.⁷⁰ These null red cells have been demonstrated to be resistant to lysis by 2M urea; however, this phenotype is not associated with shortened red cell survival or clinical symptoms.⁷¹

Antibodies and Clinical Significance

The Kidd antibodies are usually IgG but occasionally are IgM. These antibodies tend to be short-lived; therefore, they are frequently not detected before transfusion. However, they are capable of a rapid amnestic response and have been associated with severe delayed HTRs. The antibodies have rarely been associated with HDN, usually of mild severity.⁵⁶

P.520

MNS Blood Group System (ISBT 002)

SUMMARY OF IMPORTANT CHARACTERISTICS OF MNS ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
Anti-M	Seldom	IgG; some IgM	Few	Few	Common (22%)
Anti-N	Rarely	IgM; rarely IgG	Rare	Rare	Very rare (<1%)
Anti-S	Occasionally	IgG; some IgM	Yes	Yes	Common (45%)
Anti-s	Yes	IgG; rarely IgM	Yes	Yes	Very rare (<1%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The MNS blood group system was discovered in 1927. The M and N antigens get their names from the letters in the word immune, because anti-M and anti-N antibodies were discovered in the sera of rabbits immunized with human red cells. The letter I was not used because it was felt this would be confused with the number 1.^{72,73} The S antigen was named after the city in which it was discovered—Sydney, Australia.⁷³

Genes and Antigens

The MNS blood group system consists of 46 antigens: M, N, S, s, U, He, Mi^a, M^c, Vw, Mur, M^e, Vr, M^e, Mt^a, St^a, Ri^a, Cl^a, Ny^a, Hut, Hil, M^v, Far, s^d, Mit, Dantu, Hop, Nob, En^a, ENKT, N', Or, DANE, TSEN, MINY, MUT, SAT, ERIK, Os^a, ENEP, ENEH, HAG, ENAV, MARS, ENDA, ENEV, and MNTD (Table 20.1). The M and N antigens are carried on glycoprotein A, whereas the antithetical antigens, S and s, are carried on glycoprotein B. They are encoded by the GYPA, GYPB, and GYPE genes located at chromosome 4q31.21. GYPA has seven exons distributed over 60 kbp.⁴⁵ GYPB has five exons and is distributed over 58 kbp.⁴⁵ GYPA and GYPB contribute to most of the carbohydrate on the red cell membrane. The sialic acid of the O-glycans on these sialoglycoproteins results in the red cell membrane being negatively charged. This negative charge prevents red cells from sticking together, prevents red cell adherence to endothelial cells of the blood vessel walls, and protects from invasion by pathogens.^{74,74,75,76} The presence of glycoprotein A has been demonstrated to be necessary for the adhesion of

certain malarial parasites (*P. falciparum*) as well as for bacteria and viruses (e.g., influenza virus and encephalomyocarditis virus).^{76,77,78,79} and ⁸⁰ Other proposed functions of glycophorin A include regulation of transport of band 3 to the red cell membrane and complement regulation.^{70,78,81,82} and ⁸³ The main phenotypes and frequencies of the MNS blood group system are listed in Table 20.8.

Antibodies and Clinical Significance

Anti-M and anti-N antibodies are typically IgM and are reactive at cold temperatures. Antibodies against M and N are naturally occurring (environmentally stimulated). They are not generally considered to be clinically significant. Rarely, anti-M has been implicated in cases of HDN and HTR.^{61,62,63} and ⁶⁴ Anti-N has only rarely been associated with HDN or HTR. In contrast, antibodies against S, s, and U are capable of causing HTR and HDN.⁷⁰ Anti-S and anti-s tend to be IgG and occasionally are IgM. Antibodies to many low-prevalence antigens in the MNS system have also been associated with HDN.⁷⁶

P Blood Group System and Related Antigens (ISBT 003)

SUMMARY OF IMPORTANT CHARACTERISTICS OF P ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)	
P1	Rare	IgM; rarely IgG	No	Rare Common (21%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The first P system antigen was discovered by Landsteiner and Levine in 1927.⁴⁴ Initially, the system was thought to include the P, P^k, and LKE antigens, but these antigens have subsequently been assigned to the globoside antigens (see section GLOB Collection [ISBT 209]).⁴⁴

Genes and Antigens

The P blood group system consists of a single antigen: P1 (Table 20.1). P1 is the product of a galactosyltransferase encoded by the gene P1, which is located at chromosome 22q11.2-qter.⁴⁵ It has been suggested that this transferase is encoded by the gene A4GALT, but this has been contradicted by recent studies.⁵² The P1 antigen is similar to the ABO antigens because it is composed of a chain of sugars linked to glycolipids on red cells (Fig. 20.2). P1 is formed when β-D-galactose (Gal) is added in an α(1-4) linkage to paragloboside.⁴⁴ In the white population, 79% of individuals express the P1 antigen.⁴⁴

Antibodies and Clinical Significance

Anti-P1 is naturally occurring and is commonly found in individuals lacking the P1 antigen. Anti-P1 is usually IgM. It has not been reported to cause HDN and has been associated with HTR only in rare instances.⁸⁴ Identification of anti-P1 is aided by the fact that the activity of the antibodies is inhibited by hydatid cyst fluid or pigeon egg white.⁴⁴

Individuals who lack the P1 antigen who also do not express the P and P^k antigens may produce anti-P,P1,P^k, also known as anti-Tj^a. This antibody can be either IgM or IgG and has been associated with severe hemolytic reactions.^{85,86}

Lutheran Blood Group System (ISBT 005)

SUMMARY OF IMPORTANT CHARACTERISTICS OF LUTHERAN ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)	
Lu ^a	Seldom	IgM; some IgG	Mild No	Very common (92%)
Lu ^b	Seldom	IgG; some IgM	Mild No	Very rare (0.1%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

FIGURE 20.2 Differences between ABO (A) and Lewis (B) blood groups. ABO blood group antigens are synthesized in the red cells on type II oligosaccharides, but Lewis blood group antigens are produced in the plasma on type I oligosaccharides and then adsorbed onto the red cell surface. Type II oligosaccharide chains differ from type I chains in the linking position of the terminal galactose moiety. The Le (FUT3) gene encodes type III H transferase, which adds a fucose group (redcolored fucose group) to the second-last sugar moiety of the type I oligosaccharide chain. Synthesis of the Le^c and Le^d antigens does not depend on the activity of the Le gene. Fuc, l-fucose; Gal, d-galactose; Gal-NAc, d-N-acetyl-galactosamine; Glc, d-glucosamine; Glc-NAc, d-N-acetyl-glucosamine.

The first Lutheran blood group antibody (anti-Lu^a) was found in 1946 in the serum of a previously transfused patient named Lutteran. The label on the sample was misread, and the blood group system was named Lutheran.⁷⁰

Genes and Antigens

The Lutheran blood group system consists of 20 antigens: Four pairs of antigens (Lu^a/Lu^b, Lu6/Lu9, Lu8/Lu14, and Au^a/Au^b) and 11 independent antigens (Lu3, Lu4, Lu5, Lu7, Lu11, Lu12, Lu13, Lu16, Lu17, Lu20, Lu21, and LURC) (Table 20.1).⁶ The antigens are encoded by the B-CAM (LU) gene located at chromosome 19q12-q13. The gene contains 15 exons and is distributed over approximately 12 kbp.³⁹ The gene products include the Lutheran glycoprotein, which is 597 amino acids long, and a spliced version of the B-cell adhesion molecule (B-CAM), which is 557 amino acids in length.^{45,70} The Lutheran glycoproteins are members of the Ig superfamily and have been demonstrated to act as a receptor for laminin.^{87,88} The Lutheran blood group may play a role in the pathophysiology of sickle cell disease and polycythemia vera. In sickle cell disease, B-CAM and Lu are overexpressed on red cells, which may mediate increased red cell adhesion to laminin.⁸⁹ In polycythemia, there is increased phosphorylation of the Lu glycoprotein, which increases red cell adhesion.⁹⁰ The principal phenotypes of the Lutheran blood group system and their frequencies are outlined in Table 20.8.

Antibodies and Clinical Significance

The Lutheran antigens are not very immunogenic; therefore, antibodies in this system are rare.⁷⁰ Anti-Lu^a and anti-Lu^b are usually IgG and are reactive on the indirect antiglobulin test. Anti-Lu^a has not been implicated in HTR but has been implicated in mild HDN.⁷⁰ Anti-Lu^b has been associated with mild, subclinical HDN.^{91,92}

P.522

Lewis Blood Group System (ISBT 007)

SUMMARY OF IMPORTANT CHARACTERISTICS OF LEWIS ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)	
Le ^a	Seldom	IgM	No	Rare Rare (6%)
Le ^b	Seldom	IgM	No	Rare Common (22%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Lewis blood group system is different from other blood group systems, as the antigens (Le^a and Le^b) are formed in the plasma and absorbed onto the red cell membrane. This unique feature has implications for transfusion practices for several reasons: (a) transfused red cells always absorb Lewis antigens from the plasma of the transfusion recipient; hence, within several days of the transfusion, the phenotype of the circulating transfused red cells is the same as the patient's red cell phenotype; and (b) soluble antigen in transfused plasma has the potential to inhibit Lewis system antibodies that may be in the plasma of some individuals.

Genes and Antigens

The two alleles (Le and le) are inherited in Mendelian fashion. Le is the dominant allele, and le is the recessive allele. The FUT3 (Le) gene is located on chromosome 19 (19p13.3)^{93,94} and is closely linked to the FUT1 (Hh) and FUT2 (Sese) genes. There are 11 different mutations of the FUT3 gene.^{95,96} The silent le allele is due to mutations that result in defective gene products. The FUT3 gene encodes for an enzyme, $\alpha(1,3/1,4)$ fucosyltransferase (FUT3, H transferase type 3), which adds fucose molecules to carbohydrate precursor chains (Fig. 20.3). The enzyme itself is a type II membrane-bound protein of 361 amino acids.⁹⁷

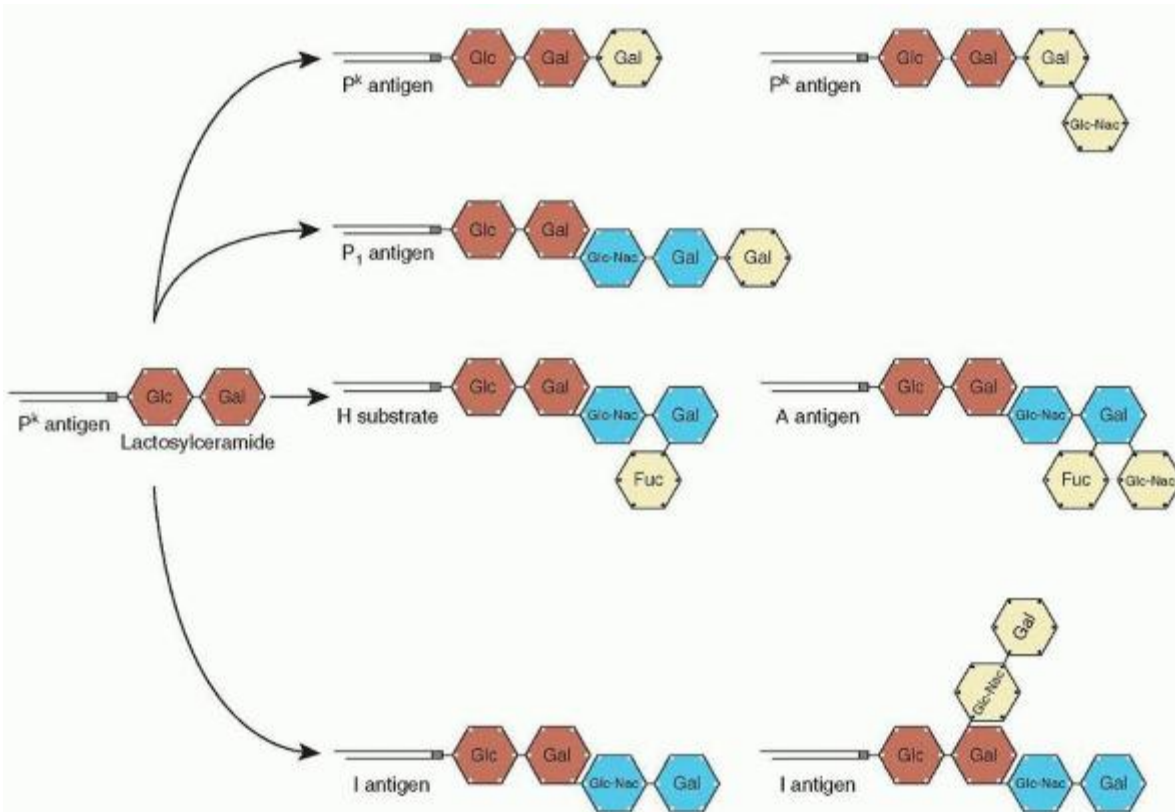

FIGURE 20.3 The relationship among ABO, P, and Ii blood group systems. These antigens are located on terminal oligosaccharides. Among these blood groups, the structure in common is lactosylceramide (red sugar moieties). Lewis blood group antigens also share similar structures, but they are not synthesized in red cells. Fuc, l-fucose; Gal, d-galactose; Gal-NAc, d-N-acetyl-galactosamine; Glc, d-glucosamine; Glc-NAc, d-N-acetyl-glucosamine.

Antigens

As mentioned previously, Lewis antigens (Le^a and Le^b) on the red cells are not intrinsic to the red cell membrane but are absorbed from the plasma onto the cells.⁹⁸ The antigenic epitopes are located at the fucose moieties of glycosphingolipids. The biosynthesis of the antigens Le^a and Le^b involves two different pathways. The formation of antigen Le^a is catalyzed by the enzyme FUT3 that adds a fucose group to the type 1 oligosaccharide precursor chain (Fig. 20.3). In individuals with FUT2 (SeSe or Sese genotypes), most type 1 oligosaccharide precursor chains are converted to an intermediate product similar to the H antigen. The intermediate product is subsequently catalyzed by the enzyme FUT3 and forms the Le^b antigen. Therefore, the phenotypes $Le(a-b+)$ and $Le(a+b-)$ are not due entirely to the FUT3 gene but depend on the presence or absence of the FUT2 (Se) gene. This relationship between the FUT2 and FUT1 genes has practical implications for the laboratory. For example, the easiest way to determine an individual's secretor status is to type his or her red cells to determine their Lewis phenotype. The $Le(a+b-)$ phenotype indicates that the individual is a nonsecretor; the $Le(a-b+)$ phenotype indicates that the individual is a secretor; and the $Le(a-b-)$ phenotype does not allow secretor status to be assigned. If the FUT2

P.523

product (FUT2) is partially active, such as in individuals with Se^w , some type 1 precursor chain is converted to Le^a antigen, and the remaining is converted to Le^b . The resultant phenotype, $Le(a+b+)$, is rare in whites but common in Asians. The fucose residual may also be added to the type 2 oligosaccharide precursor chain and forms the Le^x and Le^y antigens that are similar to ABO(H) antigens in biochemical structure.

In the Lewis blood group system, the phenotype distribution varies among different ethnic groups. The $Le(a-b+)$ phenotype is found in 70% of the white population and approximately 50% of the black population. The $Le(a-b-)$ phenotype is less common in the white population but is found in approximately 30% of the black population. The $Le(a+b+)$ phenotype is rare in both the white and black populations (Table 20.8).

In addition to red blood cells, Lewis antigens are found on other cell surfaces, such as gastric mucosa. They are also found in the lipopolysaccharide envelope of *Helicobacter pylori*.⁹⁹ Although the gastric mucosa predominately expresses Le^a and Le^b, the cell envelope of *H. pylori* mainly expresses Le^x and Le^y.⁹⁹ The relationship between the Lewis antigens and the pathogenesis of *H. pylori* infection is uncertain. The similarity of the antigens may deceive the host immune system and facilitate the colonization of *H. pylori*.¹⁰⁰ In a murine model, *H. pylori* infection has been shown to induce antibodies cross-reactive to gastric mucosa and to contribute to the development of chronic gastritis and peptic ulcers.¹⁰¹ However, this has not been firmly established in humans because no concordance in the expression of the Lewis antigen has been found between the bacteria and the host.^{102,103} Some studies showed that Le^b and H antigens on the gastric mucosa mediated the binding of *H. pylori* via a binding protein (blood group antigen-binding adhesin).^{104,105} However, other studies demonstrated that *H. pylori* adherence is not dependent on the Lewis antigen.¹⁰⁶ Similarly, it has been disputed whether blood group O is a risk factor for peptic ulcer disease.^{107,108} and ¹⁰⁹ Also, the isoform antigens Le^x and Le^y may be found as neoantigens on malignant tissue.¹¹⁰

Antibodies and Clinical Significance

Like the ABO system, antibodies specific for Lewis antigens are naturally occurring, being formed through exposure to environmental antigens. The antibodies are usually IgM, complement activating, and reactive at or below room temperature. Although Lewis antibodies have been reported to cause HTRs, this does not usually occur for several reasons. First, although Lewis antibodies can activate complement, the process is relatively slow, thus allowing the inhibitors within the complement cascade to stop the process before the membrane attack complex is activated. Second, soluble antigen present in the plasma of the transfused blood product can neutralize the antibody, preventing subsequent binding of antibody to transfused red cells. Finally, within 24 to 48 hours of transfusion, the transfused red cells absorb Lewis antigens from the patient's plasma, taking on the Lewis phenotype of the patient's own red cells. This latter mechanism also prevents delayed transfusion reactions from occurring. Lewis antibodies may be clinically relevant if the antibody causes in vitro hemolysis during serologic laboratory testing. When these "in vitro hemolytic antibodies" are detected, they should be considered clinically relevant, and antigen-negative blood should be selected for transfusion. Lewis antibodies do not cause HDN because they are IgM and do not cross the placenta. Furthermore, Lewis antigens are poorly developed on fetal red cells.

Anti-Le^a antibody is more common than anti-Le^b antibody. Both anti-Le^a and anti-Le^b antibody are found in individuals with the Le(a-b-) phenotype. In contrast, individuals with the Le(a-b-) phenotype do not develop anti-Le^a because of the presence of residual Le^a antigen in the secretions.

Diego Blood Group System (ISBT 010)

SUMMARY OF IMPORTANT CHARACTERISTICS OF DIEGO ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)
Di ^a	Yes	IgG; some IgM	Yes Rare Very common (>99.9%)
Di ^b	Yes	IgG; some IgM	Yes Rare Very rare (<0.1%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Diego blood group system consists of 22 antigens: Di^a, Di^b, Wr^a, Wr^b, Wd^a, Rb^a, WARR, ELO, Wu, Bp^a, Mo^a, Hg^a, Vg^a, Sw^a, BOW, NFLD, Jn^a, KREP, Tr^a, Fr^a, SW1, and DISK (Table 20.1).⁶

Gene and Antigens

The Diego system antigens are carried on the band 3 protein. The antigens are encoded by the gene SLC4A1, which is found at chromosome 17q12-q21 (Table 20.1). SLC4A1 contains 20 exons and is distributed over 228 kbp.⁴⁵ Band 3 is a multipass transmembrane protein that serves as an anion transporter. The Di^a antibody was initially found in the serum of a Venezuelan woman and was implicated in HDN.¹¹¹ The principal phenotypes of the Diego blood group system and their frequencies are outlined in Table 20.8. The expression of the antigen Di^a is almost exclusively restricted to populations of Mongolian descent, such as American Indians, Chinese, and Japanese.¹⁰⁰ An altered version of the band 3 protein is found in a condition known as Southeast Asian ovalocytosis. This condition may confer a degree of resistance to *Plasmodium falciparum*.¹¹²

Antibodies and Clinical Significance

Anti-Di^a and anti-Di^b are usually IgG and are detected by the indirect antiglobulin test. HDN has been reported with both anti-Di^a and anti-Di^b.^{113,114,115,116} and ¹¹⁷ HTR is rare but has been reported.¹¹⁸

Yt Blood Group System (Cartwright) (ISBT 011)

SUMMARY OF IMPORTANT CHARACTERISTICS OF YT ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
Yt ^a	Rare	IgG	No	Yes	Very rare (0.2%)
Yt ^b	Rare	IgG	No	Yes	Very common (91.9%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Yt system consists of two antigens: Yt^a and Yt^b (Table 20.1). The system was named after Cartwright, the individual discovered producing the antibody. Because all of the other letters in the individual's name were already being used, the last letter, T, was selected. The letter Y was placed first to denote "why not T?".⁷⁰

P.524

Gene and Antigens

The AChE gene is located at chromosome 7q22. It encodes for an acetylcholinesterase, which is a dimerized glycosyl phosphatidylinositol (GPI)-linked glycoprotein in the red blood cell membrane. Its function is unknown; however, the molecule is enzymatically active. Yt^a and Yt^b antigens result from a single amino acid substitution, which does not appear to affect the enzymatic activity of acetylcholinesterase.¹¹⁹ The antigens are antithetical. Yt^a occurs with a frequency of approximately 99%, and Yt^b has a frequency of approximately 8% (Table 20.8).¹²⁰ Because they are carried on a GPI-linked protein, Yt antigens may be absent or reduced in individuals with paroxysmal nocturnal hemoglobinuria (see Chapter 31).

Antibodies and Clinical Significance

Antibodies against the Yt antigens are usually IgG. They do not activate complement. Yt antibodies have been implicated in delayed HTR but not in HDN.¹¹²

Xg Blood Group System (ISBT 012)

SUMMARY OF IMPORTANT CHARACTERISTICS OF XG ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
Xg ^a	No	IgG	No	No	Common (males, 34.4%; females, 11.3%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Xg blood group system consists of two antigens: Xg^a and CD99 (Table 20.1). The Xg^a antigen was discovered in 1962 by Mann in the serum of a multiply transfused male. Because the antigen frequency appeared to differ between males and females, the antigen was named Xg^a, as it appeared to be controlled by the X chromosome. The γ in the name stands for Grand Rapids, the hometown of the patient.¹²¹

Gene and Antigens

The gene encoding Xg^a, XG, is found at Xp22.32. The gene is not subject to lyonization or X inactivation. The gene that encodes CD99, now also named CD99 (previously MIC2), is closely linked to XG. The Xg^a antigen is located on a sialoglycoprotein. The antigen is only weakly expressed on the red cells of infants. The Xg^a antigen is resistant to treatment by sialidase and dithiothreitol (DTT); however, it is sensitive to treatment with proteolytic enzymes. The principal phenotypes of the Xg blood group system and their frequencies are outlined in Table 20.8.

Antibodies and Clinical Significance

Anti-Xg^a antibodies are usually IgG and may be able to activate complement. Anti-Xga can be naturally occurring.¹²² Alloantibodies to CD99 have been detected in only two healthy individuals and are not thought to be clinically significant.¹²² There have been no documented cases of HTR or HDN with these antibodies.

Scianna Blood Group System (ISBT 013)

SUMMARY OF IMPORTANT CHARACTERISTICS OF SCIANNA ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	HDNHTR	Frequency of Antigen-Negative Blood (White Population)
Sc1	No	IgG	Rare No	Very rare (<1%)
Sc2	No	IgG	Rare No Very common (>99%)	

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Scianna blood group system consists of seven antigens: Sc1, Sc2, Sc3, Rd, STAR, SCER, and SCAN (Table 20.1).

Gene and Antigens

The gene for this system, ERMAP, is located on chromosome 1p34 and is linked to Rh. ERMAP encodes a glycoprotein (erythroid membrane-associated protein), the function of which is not known. However, based on its structure, ERMAP is known to be a member of the butyrophilin-like family of the immunoglobulin superfamily.¹²³ The Sc1 antigen is a high-frequency antigen, with the incidence in most populations being close to 99.9% (Table 20.8).⁴⁵ Sc2 is antithetical to Sc1 and is present in approximately 1% of the population.⁴⁵ The antigens are resistant to treatment of red cells with proteolytic enzymes such as papain, ficin, trypsin, α-chymotrypsin, and sialidase.⁷⁰

Antibodies and Clinical Significance

The Scianna antibodies are usually IgG. Scianna antibodies can activate complement and have been reported to cause mild HDN.^{124,125,126} The antibodies have not been associated with severe HTR.^{125,126}

SUMMARY OF IMPORTANT CHARACTERISTICS OF DOMBROCK ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood (White Population)	
			HDN	HTR
Do ^a	Rare	IgG	No	Yes Common (33.3%)
Do ^b	Rare	IgG	No	Yes Common (17.2%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

Dombrock Blood Group System (ISBT 014)

The Dombrock blood group system consists of eight antigens: Do^a, Do^b, Gy^a, Hy, Jo^a, DOYA, DOMR, and DOLG (Table 20.1).^{4,127}

Gene and Antigens

The gene for the Dombrock blood group system, ART4 (or DO), is found at chromosome 12q13.2-q13.3.¹²⁸ The antigens P.525

in the Dombrock system have been demonstrated to be carried on a GPI-linked glycoprotein.^{129,130,131} and ¹³² Homology studies suggest that the Dombrock glycoprotein is a member of the adenosine 5'-diphosphate ribosyl-transferase ectoenzyme gene family and has been identified as ADP-ribosyltransferase 4 (ART4).^{131,132} and ^{133,134,135} However, the function of this molecule is uncertain, as no enzymatic activity has been demonstrated on the red cells and no pathology has been associated with absence of this glycoprotein.¹³⁵

The antigens Do^a and Do^b are antithetical. The frequencies of the three main phenotypes defined by these antigens are listed in Table 20.8. The antigens Gy^a, Hy, and Jo^a are high-incidence antigens, with gene frequencies of >99% in all

populations studied.¹³⁶ The antigens are resistant to papain or ficin treatment but sensitive to trypsin, pronase, or DTT (200 mmol/L) treatment.¹³³

Antibodies and Clinical Significance

The Dombrock antibodies are usually IgG and do not activate complement. They have not been associated with clinical HDN, but the antibodies have been associated with severe HTR.^{135,137,138} and¹³⁹ A baby born to a mother with an anti-DOMR antibody required phototherapy for hyperbilirubinemia.⁴

Colton Blood Group System (ISBT 015)

SUMMARY OF IMPORTANT CHARACTERISTICS OF COLTON ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
Co ^a	Yes	IgG	Yes	Yes	Very rare (0.3%)
Co ^b	Yes	IgG	No	Yes	Very common (90.3%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Colton blood group system was discovered in 1967. It consists of three antigens: Co^a, Co^b, and Co3 (Table 20.1).

Gene and Antigens

The Colton blood group antigens are encoded by a gene located at 7p14. The gene, AQP1 (CO), contains four exons distributed over 2.2 kbp.⁴⁵ The gene encodes a glycoprotein called the channelforming integral protein-1 (CHIP-1) or aquaporin 1 (AQP1).¹⁴⁰ AQP1 functions as a water transport channel. The antigen is strongly expressed in the proximal tubules and cortical collecting ducts of the kidney and is responsible for 80% of water reabsorption in the kidney. In red cells, AQP1 is responsible for osmotic water permeability.¹ Most individuals with the null phenotype, Co(a-b-), have red cells with markedly reduced osmotic water permeability but no obvious phenotype abnormality and are apparently healthy¹; however, a Colton-deficient individual with congenital dyserythropoietic anemia has been described.¹⁴¹ Also, Colton-deficient individuals have been demonstrated to develop an inability to concentrate urine after water deprivation.¹⁴² The principal phenotypes of the Colton blood group system and their frequencies are outlined in Table 20.8.

Antibodies and Clinical Significance

Antibodies against the Colton blood group antigens are usually IgG and may activate complement. These antibodies are clinically significant and have been implicated in acute and delayed transfusion reactions.^{143,144,145,146,147} and¹⁴⁸

Landsteiner-Wiener Blood Group System (ISBT 016)

SUMMARY OF IMPORTANT CHARACTERISTICS OF LANDSTEINER-WIENER ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
LW ^a	Yes	IgG; some IgM	Yes	Yes	Very rare (<1%)
LW ^b	Yes	IgG; some IgM	Yes	Yes	Very common (>99%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Landsteiner-Wiener blood group system consists of three antigens: LW^a, LW^{ab}, and LW^b (Table 20.1).

Genes and Antigens

The gene encoding the Landsteiner-Wiener blood group system antigens, ICAM-4, is found at chromosome 19p13.2-cen. The ICAM-4 gene contains three exons distributed over 2.6 kbp.⁴⁵ It encodes the LW glycoprotein, also known as intracellular adhesion molecule 4 (ICAM4). The LW glycoprotein is associated with the Rh proteins in the red blood cell membrane as part of a multiprotein macromolecular complex.¹⁴⁹ The LW glycoprotein is an intercellular adhesion molecule and has been demonstrated to bind to CD11/CD18 integrins located on leukocytes.¹⁵⁰ It is hypothesized that its

function may involve being a marker for lymphocyte maturation and differentiation.⁷⁰ LW_{null} red cells appear to have normal morphology and survival.¹⁴⁹

The frequencies of the Landsteiner-Wiener blood group system phenotypes are outlined in Table 20.5. LW^a is the most commonly expressed antigen, found in more than 99% of whites. The expression of LW antigens is influenced by the expression of the Rh blood group system D antigen. Individuals who are D antigen-positive have increased expression of LW antigens compared to those individuals who are D antigen-negative.¹⁵¹

Antibodies and Clinical Significance

Antibodies to the LW antigens are usually IgG but are occasionally IgM. The antibodies have been associated with mild HDN and HTR. Production of LW autoantibodies may occur in conditions associated with transient loss of LW antigens. Conditions associated with loss of LW antigens include pregnancy, Hodgkin disease, lymphoma, leukemia, sarcoidosis, and solid malignancies.^{70,112}

P.526

Chido/Rodgers Blood Group System (ISBT 017)

SUMMARY OF IMPORTANT CHARACTERISTICS OF CHIDO/RODGERS ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
Ch	No	IgG	No	No	Rare (2%)
Rg	No	IgG	No	No	Rare (2%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Chido and Rodgers system consists of nine antigens: Ch1 to 6, Rg1, Rg2, and WH (Table 20.1). The Chido antigen was initially described by Harris et al.¹⁵² The antigen was described as “nebulous” because the antigen strength was variable. The Chido and Rodgers system is not composed of true red cell antigens, as they are not actually located on intrinsic structures of the red cell. Instead, they are on the fourth component of the complement system (C4), which becomes bound to red cells. However, the antigens are detected on the surface of red cells by conventional methods and were therefore initially considered to be red cell antigens and were included in the ISBT terminology as the 17th system (ISBT 017).

Genes and Antigens

The genetic loci of the Rodgers and Chido antigens are closely linked and are located on chromosome 6p21.3 in genes closely linked to major histocompatibility complex (MHC) II. Both genes encode complement components. The C4B (CH) gene contains 41 exons and encodes for C4b.⁴⁵ The C4A (RG) gene contains 41 exons distributed over 21 kbp and encodes for C4a.⁴⁵ The Chido antigen is located on the C4d fragment of C4b.^{153,154} and ¹⁵⁵ The expression of the antigen is variable, as it is determined by the concentration of plasma complement, which is genetically determined.¹⁵⁶ The Rodgers antigen is located on the C4a component of complement.^{153,155} The principal phenotypes of the Chido/Rodgers blood group system and their frequencies are outlined in Table 20.8. Ch1 to 6 and Rg1 and Rg2 have frequencies >90%, whereas WH has a frequency of approximately 15%. The antigens are sensitive to treatment with proteases and resistant to treatment with sialidase, DTT, and acid.

Inherited low levels of C4 have been demonstrated to be associated with various autoimmune disorders, including autoimmune chronic active hepatitis.^{157,158} Individuals who are Ch-(lack C4b) have an increased risk of bacterial meningitis. Individuals who are Rg- (lack C4a) have an increased risk of systemic lupus erythematosus.^{158,159}

Antibodies and Clinical Significance

Antibodies in the Chido/Rodgers system are usually IgG and do not activate complement. They are not clinically significant. Antibodies to these antigens are typically found in individuals who have been transfused. They generally do not cause HTR but may result in anaphylactic reactions if large volumes of plasma are transfused.^{160,161} These antibodies have not been implicated in HDN.

Kx Blood Group System (ISBT 019)

SUMMARY OF IMPORTANT CHARACTERISTICS OF KX ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
Kx	No	IgG	No	No	Very rare (<0.1%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Kx blood group system consists of one antigen: Kx (Table 20.1).

Genes and Antigens

The Kx antigen is carried on the XK protein, which is encoded by the XK gene. The XK gene is located on the short arm of the X chromosome (Xp21.1). The structure of XK resembles a glutamate transporter; however, its actual cellular function has not yet been determined.⁶⁰ In the red blood cell membrane, the XK protein is found in a complex with the Kell glycoprotein. The two proteins are covalently linked by a disulfide bond.⁵⁹ It is thought that the expression of the XK protein is required for the normal expression of the Kell antigens on red cells.

The XK protein has the structure of a membrane transporter protein; however, its function is not known.¹⁶² Patients with absent XK, due to gene deletions or mutations, are said to have the McLeod syndrome. The McLeod phenotype is inherited in an X-linked pattern, unlike the KEL gene, which has an autosomal mode of inheritance.⁶⁰ The McLeod syndrome is a condition occurring in males characterized by decreased expression of the Kell blood group system antigens, acanthocytes, hemolytic anemia, and elevated serum creatinine kinase.¹ Associated symptoms include muscle wasting, decreased deep tendon reflexes, choreiform movements, and cardiomyopathy.⁵⁶ The McLeod phenotype may also occur in patients with X-linked chronic granulomatous disease. X-linked chronic granulomatous disease has been demonstrated to occur because of deletion of or mutations in the CYBB gene, which is also located on the X chromosome at a location discrete from that of the KEL locus. The association between the two disorders is due to deletions of parts of the X chromosome that include both genes.⁵⁶ Other X-linked conditions that have been associated with the McLeod phenotype include retinitis pigmentosa and Duchenne muscular dystrophy.^{163,164}

Antibodies and Clinical Significance

Patients who lack the Kx antigen form alloantibodies if they are transfused with antigen-positive blood. Patients with the McLeod phenotype who have been transfused have been reported to form anti-Kx.^{143,165} It is suggested that these patients receive Kx-negative blood, but there are no reports of the antibody causing HDN or HTR. Furthermore, some patients without clinical or hematologic features of the McLeod syndrome have been demonstrated to form an IgG autoantibody with Kx specificity.^{165,166} The autoantibody does not appear to cause hemolysis.

P.527

Gerbich Blood Group System (ISBT 020)

SUMMARY OF IMPORTANT CHARACTERISTICS OF GERBICH ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
Ge2, Ge3, Ge4	Rare	IgG	Rare	Rare	Very rare (<0.1%)
Wb, Ls ^a , An ^a , Dh ^a	Rare	IgG	Rare	Rare	Very common (>99%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Gerbich blood group system was discovered in 1960 and is named for a patient who lacked the antigen, Mrs. Gerbich.⁷⁰

Gene and Antigens

The Gerbich blood group system contains 11 antigens: Ge2, Ge3, Ge4, GEPL, GEAT, and GET1 which occur at high frequencies, and Wb, Ls^a, An^a, Dh^a, and GEIS, which occur at low frequencies (Table 20.1). The principal phenotypes of the Gerbich blood group system and their frequencies are outlined in Table 20.8. The antigens are encoded by the GYPC gene

on chromosome 2 (2q14-q21).¹³² The gene contains four exons distributed over 13.5 kbp.⁴⁵ The antigens are carried on glycoprotein C or glycoprotein D, or both. The functions of glycoprotein C and glycoprotein D are thought to involve the structural integrity of the red cell membrane, as the glycoproteins are involved in linking the red cell membrane and the membrane skeleton.¹⁶⁷ This is supported by the fact that red cells deficient in the Gerbich antigens, called the Leach phenotype, are elliptocytes.¹⁶⁸ Glycoprotein C can serve as a binding site for *P. falciparum*.¹⁶⁹

Antibodies and Clinical Significance

The antibodies against the Gerbich blood group system tend to be IgG. These antibodies have only rarely been reported to cause HDN or HTR.^{70,170,171}

Cromer Blood Group System (ISBT 021)

SUMMARY OF IMPORTANT CHARACTERISTICS OF CROMER ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood		
			HDN	HTR	(White Population)
Cr ^a	Seldom	IgG	No	Yes	Very rare (<1%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Cromer blood group system was discovered in 1965 and named after Mrs. Cromer, the first patient found to produce the antibodies.⁷⁰

Genes and Antigens

The Cromer blood group system consists of 18 antigens: Cr^a, Tc^a, Tc^b, Tc^c, Dr^a, Es^a, IFC, WES^a, WES^b, UMC, GUTI, SERF, ZENA, CROV, CRAM, CROZ, CRUE, and CRAG. (Table 20.1). The antigens in the Cromer blood group system are encoded by the CD55 (DAF or CROM) gene located at chromosome 1q32. The gene contains 11 exons and is distributed over 40 kbp.⁴⁵ The antigens are located on a glycoprotein called decay accelerating factor (DAF). DAF accelerates the decay of C3 and C5 convertases, thus inhibiting the amplification of complement activation by both the classic and alternate pathways. DAF is also a receptor for *Escherichia coli* and enterovirus.¹⁷² Individuals with the null phenotype of the Cromer system, known as the Inab phenotype, have been described but do not have significant complement-induced lysis in vivo.¹⁷³

Tc^a, Tc^b, and Tc^c are antithetical antigens, as are WES^a and WES^b. Tc^b, Tc^c, and WES^a are low-incidence antigens, whereas the rest are high-incidence antigens^{138,174} (Table 20.8).

Antibodies and Clinical Significance

Antibodies to Cromer antigens do not cause HDN, perhaps because DAF is strongly expressed on the apical surface of trophoblasts and, therefore, absorbs antibodies from the maternal serum.^{1,175} Antibodies to Cromer antigens have not been implicated in HTR, likely because the placenta is a rich source of fetal-derived DAF which is thought to adsorb the antibodies.^{176,177}

Knops Blood Group System (ISBT 022)

SUMMARY OF IMPORTANT CHARACTERISTICS OF KNOPS ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood		
			HDN	HTR	(White Population)
Kn ^a	No	IgG	No	No	Very rare (<1%)
Kn ^b	No	IgG	No	No	Very common (>99.9%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Knops blood group system was established in 1991. It is named after Mrs. Knops, the first antibody producer.⁷⁰

Genes and Antigens

The Knops system consists of eight antigens and one provisional antigen: Kn^a, Kn^b, McC^a, S11, Yk^a, McC^b, S12, and KCAM. S13 is a provisional antigen (Table 20.1). Most of the antigens are common, occurring with a prevalence of >90% in most populations (Table 20.8). The S11 antigen occurs with a much greater prevalence in white populations (98%) than in black populations (60%).¹ Kn^b occurs at a low incidence.

The antigens in the Knops blood group system are encoded by the CR1 (KN) gene found at chromosome 1q32.⁴⁵ The antigens are found on a glycoprotein called complement receptor 1 (CR1) that is also known as CD35. The gene is located within the regulation of the complement activation cluster. CR1 is a member of the complement control family. It inhibits both the classic and alternate pathways of complement activation by cleavage of C4b and C3b, thus protecting the red cells from hemolysis. It is hypothesized that low levels of CR1 on red cells may increase deposition of immune complexes on blood vessel walls, resulting in damage to the blood vessels.¹⁷⁸ Some antigens in the Knops blood group system may act as a binding site for *P. falciparum*.

Antibodies and Clinical Significance

Antibodies in the Knops blood group system are usually IgG and do not bind complement.⁷⁰ They have not been implicated in HDN or HTR.

P.528

Indian Blood Group System (ISBT 023)

SUMMARY OF IMPORTANT CHARACTERISTICS OF INDIAN ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
In ^a	No	IgG	No	No	Very common (>99%)
In ^b	Seldom	IgG	No	Rare	Very rare (<1%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Indian blood group was so named because 4% of Indians from Bombay express the antigen.⁷⁰

Genes and Antigens

The Indian blood group system consists of four antigens: In^a, In^b, INFI, and INJA (Table 20.1). The antigens of the Indian blood group system are encoded by the CD44 gene located at chromosome 11p13. The gene contains at least 19 exons and is distributed over 50 kbp.⁴⁵ CD44 is thought to be the major human hyaluron receptor and also may bind fibrinogen, laminin, collagen, and osteopontin.¹ The interaction between CD44 and hyaluron is likely required for the adhesion of lymphoid and erythroid cells to the bone marrow stroma during lymphopoiesis and erythropoiesis. A patient with a novel form of congenital dyserythropoietic anemia and CD44 deficiency was noted to have the In(a-b-) phenotype.¹⁷⁹ The principal phenotypes of the Indian blood group system and their frequencies are outlined in Table 20.8.

Antibodies and Clinical Significance

Antibodies in the Indian system are usually IgG and do not activate complement.⁷⁰ These antibodies have not been associated with HDN, but anti-In^b has been implicated in one immediate HTR.¹⁸⁰

Ok Blood Group System (ISBT 024)

SUMMARY OF IMPORTANT CHARACTERISTICS OF OK ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
Ok ^a	No	IgG	No	No	Very rare (<0.1%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Ok blood group system consists of one antigen: Ok^a, OKGV, and OKVM (Table 20.1).³ Antibodies against the Ok^a antigen were initially identified in 1979 in the serum of a Japanese woman, Mrs. Okbutso.⁷⁰

Genes and Antigens

The Ok^a antigen is encoded by the BSG (OK) gene, which is located at 19p13.3. The BSG gene contains seven exons distributed over 1.8 kbp.⁴⁵ The gene encodes for basigin or CD147, an extracellular matrix metalloproteinase inducer. Basigin has been shown to induce the production of matrix metalloproteinase in fibroblasts and in tumor cells. It plays a role in tumor angiogenesis as it induces expression of vascular endothelial growth factor and hyaluronase.^{3,181} In addition,

it regulates lymphocyte responsiveness, monocarboxylate transporter expression and spermatogenesis. It also functions as a signaling receptor for the cyclophilin family of proteins^{3,182}. The Ok^a antigen is resistant to treatment with proteases, sialidase, DTT, and acid.

Antibodies and Clinical Significance

Antibodies in the initial patient with anti-Ok^a were IgG and did not activate complement. Anti-Ok^a has not been associated with HTR or HDN, but it has been demonstrated to cause decreased red cell survival.

RAPH Blood Group System (ISBT 025)

SUMMARY OF IMPORTANT CHARACTERISTICS OF RAPH ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
MER2	No	IgG	No	No	Rare (8%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The RAPH blood group system consists of one antigen: MER2 (Table 20.1). The system is named after the first patient known to have antibodies against the antigen. The MER2 antigen was given system status in 1999.

Genes and Antigens

The gene, CD151 (RAPH), is found on chromosome 11p15.5 and it encodes for the CD151 protein. Although the exact function of CD151 is unknown, anti-MER2 was found in three individuals. All individuals had renal failure and two had sensorineural deafness and pretibial epidermolysis bullosa.^{183,184} This suggests that CD151 is likely essential for the assembly of the kidney basement membrane, is a component of the inner ear, and has some functional significance in the skin.^{183,185} Ninety-two percent of English blood donors are positive for MER2 (Table 20.8).⁷⁰

Antibodies and Clinical Significance

Antibodies against MER2 are IgG. They have not been documented to cause HDN but there is a case report of an anti-MER2 possibly associated with HTR.¹⁸⁴

John Milton Hagen Blood Group System (ISBT 026)

SUMMARY OF IMPORTANT CHARACTERISTICS OF JOHN MILTON HAGEN ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood HDNHTR(White Population)		
JMH1	No	IgG	No	No	Very rare (<0.1%)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

P.529

The John Milton Hagen blood group system consists of six antigens: JMH, JMhk, JMhL, JMhG, JMhM, and JMhQ (Table 20.1). It was recognized as a system by the ISBT Working Party in July 2000.¹⁸⁶

Genes and Antigens

The JMH antigen is encoded by SEMA7A, which is located on chromosome 15q22.3-q23. The gene product is semaphoring 7A. The function of semaphoring 7A is unknown.

Antibodies and Clinical Significance

Antibodies against JMH are usually autoimmune and do not tend to be clinically significant. Individuals producing alloanti-JMH have been reported.^{187,188} The antibodies tend to be IgG. They have not been documented to cause HDN or HTR.

I Blood Group System (ISBT 027)

SUMMARY OF IMPORTANT CHARACTERISTICS OF I ANTIBODIES (INCLUDING I COLLECTION)

Antibody	Clinically	Antibody	HDNHTR	Frequency of Antigen-Negative Blood	
-----------------	-------------------	-----------------	---------------	--	--

Specificity	Significant	Class	(White Population)		
I	Seldom	IgM	No	No	Very uncommon (adults)
i	Seldom	IgM	No	No	Very common (adults)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The I blood group system consists of one antigen: I (Table 20.1). This antigen was previously classified in the Ii Collection but was recognized as a blood group system in 2004.^{6,186} The i antigen, the precursor of the I antigen, provisionally remains within the Ii Collection of antigens (ISBT 207).

Genes and Antigens

The I antigen is located on the same carbohydrate chains on which the ABH antigens are located (Fig. 20.3). The enzyme responsible for the conversion of i-active straight chains to I-active branched chains is N-acetylglucosaminyltransferase A and is encoded by GCNT2 on chromosome 6p24.2.

Antibodies and Clinical Significance

The anti-I antibody is found as an IgM autoantibody in most normal individuals. The antibody is generally reactive at low temperatures and is not clinically significant. Anti-I cold agglutinins increase in titer after infection with *Mycoplasma pneumoniae* and tend to be polyclonal in nature.¹⁸⁹ Monoclonal anti-I autoantibodies are found in high titers in cold hemolytic agglutinin disease. These antibodies are clinically significant and cause hemolysis. Anti-I alloantibodies are rare because the i phenotype is very uncommon. When they occur in adults with the i phenotype, they are clinically significant and can cause hemolysis.

Globoside Blood Group System (ISBT 028)

SUMMARY OF IMPORTANT CHARACTERISTICS OF GLOBOSIDE ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	Frequency of Antigen-Negative Blood (White Population)	
			HDN	HTR
P	Yes	IgG (biphasic activity)	Very rare	

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Globoside blood group system consists of one antigen: P (Table 20.1). This antigen was previously classified in the Globose Collection of antigens along with Pk and LKE. These antigens were initially considered to be part of the P blood group system and are related to the P1 antigen.

Genes and Antigens

The P antigen has been demonstrated to be on almost all human red blood cells.⁴⁴ It is synthesized from globotriaosylceramide by the action of UDP-N-acetylgalactosaminyltransferase (P synthase) encoded by B3GALNT1 (B3GALT3) found at chromosome 3q25. The function of the P antigen is not known. It has been demonstrated to be a receptor for parvovirus B19 and individuals who lack this antigen have been demonstrated to be naturally resistant to parvovirus B19 infection.^{190,191}

Antibodies and Clinical Significance

Autoantibodies against the P antigen are uncommon and may be idiopathic or secondary to other disorders such as syphilis and infections with various agents (e.g., measles, mumps, Epstein-Barr virus, cytomegalovirus, varicella-zoster virus, adenovirus, influenza A, *M. pneumoniae*, *Haemophilus influenzae*, and *E. coli*).¹⁹² Anti-P has been implicated in paroxysmal cold hemoglobinuria and is known as the Donath-Landsteiner antibody. This antibody is IgG and has biphasic activity in that it binds to red blood cells and fixes complement component C1 at low temperatures (0° to 4°C) and causes hemolysis at higher temperatures. Please see Chapter 31 for a more complete discussion of paroxysmal cold hemoglobinuria.

Gill Blood Group System (ISBT 029)

The Gill Blood group system consists of one antigen: Gil (Table 20.2).

SUMMARY OF IMPORTANT CHARACTERISTICS OF GILL ANTIBODIES

Antibody Specificity	Clinically Significant	Antibody Class	HDN/HTR	Frequency of Antigen-Negative Blood (White Population)	
GIL	No	IgG	No	Possibly (rare)	Very rare

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.
P.530

Genes and Antigens

The Gil antigen is located on the glycerol transporter aquaporin 3 encoded by the AQP3 gene found on chromosome 9p13.¹⁹³ Aquaporin 3 functions as a water and glycerol channel.¹⁹⁴

Antibodies and Clinical Significance

The Gil antigen is a high-frequency antigen. It has not been implicated in HDN but may have possibly been associated with one HTR.¹⁹⁵

RhAG Blood Group System (ISBT 030)

The RhAG Blood group system is the newest blood group system. The RhAG blood group system consists of 4 antigens: two high-frequency antigens, Duclos and DSLK (Duclos-like), and 2 low-frequency antigens, OI^a and RHAG4 (Table 20.2). The antigens are encoded by the RHAG gene located at chromosome 6p12.3.

Genes and Antigens

RHAG is the ancestral gene from which RHCE and RHD arose.¹⁹⁶ The RhAG protein consists of 409 amino acids. It associates with the Rh proteins and forms the Rh-core complex in the red cell membrane.¹⁹⁷ As described earlier, the RhAG protein is important in that it must be present for the expression of the Rh antigens. This may occur because of mutations or deletions in RHAG or the Rh antigens. If the RhAG protein is not present, the red cells lack Rh antigens and are said to be Rh_{null}.¹⁹⁶ The RhAG protein is also believed to contribute to the red cell membrane structure through its interactions with various proteins including band 3, glycophorin A and B, LW, and CD47.¹⁹⁶ Further, it has been demonstrated to be an ammonia transporter.^{47,198}

Antibodies and Clinical Significance

There are no reports of alloantibodies against the RhAg antigens.

Low-incidence Antigens (700 Series)

An antigen is considered to be a low-incidence antigen if (a) it occurs in <1% of a population tested; (b) it is not part of an existing blood group system or related closely enough to another antigen to merit collection status; and (c) it is serologically distinct from other low-incidence antigens. Furthermore, to allow identification of further examples, red cells containing the antigen and antibody must be available. Table 20.3 lists the 18 low-incidence antigens that comprise the 700 series of the ISBT terminology.

Typically, these antibodies arise as a result of no known stimulus. Occasionally, antibodies to these antigens may be discovered in mothers of neonates with HDN. Because of the low frequency of these antigens, initial screening against a standard red cell panel is negative; however, the serum is positive when tested against paternal cells. Family studies often detect other individuals with the antigen.

High-incidence Antigens (901 Series)

An antigen is considered to be a high-incidence antigen if it is found on >90% of individuals in populations tested. Antigens that are found in >99% of the population are termed public antigens. As noted previously, high-incidence antigens were initially included in the 900 series but are now contained in the 901 series. The 901 series currently contains six antigens (Table 20.4).

The significance of high-incidence antigens is that the rare individual lacking a high-incidence antigen may experience severe HTRs when transfused with antigen-positive blood. Because by definition the majority of the population expresses the antigen, it is very difficult to find compatible blood for such a patient.

Collections of Antigens

In the ISBT terminology, related sets of antigens (genetically, biochemically, or serologically) that cannot correctly be classified as systems, as they have not been shown to be genetically distinct from all existing systems, are designated as collections. Six collections are currently recognized: Cost, li, Er, GLOB, Le^c/Le^d, and Vel and MN/CHO (Table 20.2).

li Collection (ISBT 027)

The I antigen was described in 1956 by Weiner et al.¹⁹⁹ The antigen was named I for individuality. In 2004, the I Blood Group System (ISBT 027) was created and now contains the I antigen. The i antigen provisionally remains within the li Collection of antigens.^{6,200}

Genes and Antigens

The li antigens are synthesized on red blood cells and are located on the same carbohydrate chains on which the ABH antigens are located (Fig. 20.2). The I antigens are located below the ABH antigens. The antigens are synthesized by a regulated, stepwise addition of sugars by a series of glycosyltransferases.²⁰⁰ The i antigen consists of the disaccharides, galactose-N-acetyl-glucosamine, linked in a straight, nonbranched chain. The I antigen consists of the linear chains modified into branched chains.²⁰¹ Adult red blood cells express predominantly the I antigen. Conversely, fetal cells predominantly express the i antigen with little or no I expression. However, during the first 18 months of life, the infant's red cells gradually express more I and less i. Very rarely, adult red blood cells express predominantly the i antigen. The gene involved is most likely GCNT2 (IGnt), which is found on chromosome 6p24.2.²⁰⁰

Antibodies and Clinical Significance

The anti-i autoantibody may commonly be found in individuals with lymphoproliferative disorders such as chronic lymphocytic leukemia, lymphoma, and Hodgkin disease. Patients with mononucleosis secondary to Epstein-Barr virus infection may have transient anti-i, which causes hemolysis.

GLOB Collection (ISBT 209)

The GLOB or globoside collection of antigens includes Pk and LKE antigens (Table 20.2). The antigens of the GLOB collection were initially considered to be part of the P blood group system, and they are related to the P1 antigen. Prior to 2004, this collection also included the P antigen.

PLATELET ANTIGENS

Alloantibodies directed against platelet surface antigens can cause isolated thrombocytopenia. The antibodies most commonly play a role in neonatal alloimmune thrombocytopenia (NAT) and posttransfusion purpura (PTP), but they also mediate the destruction of platelets in passive alloimmune thrombocytopenia (PAT), posttransfusion refractoriness (PTR), and transplantation-associated thrombocytopenia (TAT).³⁰ Although the mechanisms of platelet clearance are understood in some disorders (e.g., NAT), the platelet-antibody interaction and resulting thrombocytopenia are less well understood in others (e.g., PTP). Limiting factors include the lack of appropriate investigational technology and the rarity of some of the disorders. Until recently, the identification of

P.531

incompatible antigens relied on serologic methods that require well-characterized antisera. After the identification of the genetic basis for the major platelet alloantigens, a number of different genotyping techniques were developed. This advance has made it possible for more laboratories to perform platelet alloantigen investigations based on DNA methodology rather than relying on the requirements for sufficient platelets and appropriate typing antisera for serology-based phenotyping.

Immunization to platelet alloantigens can occur in normal individuals when exposed during pregnancy, transfusion, or transplantation to alloantigens they lack. Unlike red cell alloantibodies, it is uncommon for alloantibodies against platelets to form spontaneously.

Platelet Glycoprotein Polymorphisms

Alloantigens are expressed on platelet proteins, glycoproteins, and carbohydrates. Many of these proteins are found exclusively on platelets as complexes containing two or more different polypeptide chains and are termed platelet-specific proteins. Most of these platelet glycoproteins also function as cell receptors. These receptors play a major role in the interaction of platelets with the damaged vessel wall (adhesion) and with other platelets (aggregation).

On platelets, most alloantigens are caused by a structural change in a protein due to an alternate amino acid that is encoded by a polymorphism in the gene. Many of these polymorphisms arise from single base pair mutations within the gene. To date, all the polymorphisms on platelets have been diallelic, with only a single mutation recorded at each respective locus (Fig. 20.4).

Because of the tremendous variability in the human genome among individuals, a typical person can be heterozygous for 24,000 to 40,000 substitutions, each encoding a different amino acid.^{202,203} and ²⁰⁴ Thus, it is likely that there are many polymorphisms that encode variant forms of platelet proteins that have yet to be identified.

Nomenclature

Like red cells, the initial platelet alloantigens were described and characterized based on the binding of alloantibodies from immunized individuals to platelet proteins. Before the advent of glycoprotein-specific assays, the rate of identifying novel alloantigens was low, and the practice of identifying the antigen by the first few letters of the proband surname was sufficient. Alleles were noted with a superscript a or b and were assigned in the temporal order in which they were identified with serum from alloimmunized patients (e.g., Ko^a Ko^b; Bak^a Bak^b). However, a rapid increase in the detection rate of new antigens also coincided with confusing reports when the same alloantigen was discovered more than once by different investigators and given more than one designation.

This prompted a reconsideration and standardization of the nomenclature in the form of the human platelet antigen (HPA) system.²⁰⁵ The system was based on organizing the antigens based on their recognition by specific alloantisera. HPA designations were assigned to antigens at a certain locus as they were reported chronologically in the literature. However, to establish consistency in the terminology, the high- and low-frequency alleles were assigned a and b, respectively. Thus, the PL^{A1}/PL^{A2} antigens became HPA-1a/-1b, and the Bak^a/Bak^b antigens became HPA-3a/-3b. For a few loci, alloantibodies to the low-frequency antigen had been reported first, which resulted in the reversal of a/b allele assignments (e.g., HPA-2a/-2b = Ko^b/Ko^a; HPA-5a/-5b = Br^b/Br^a). It was proposed that the Platelet Nomenclature Committee, a joint panel of the ISBT and the International Society of Thrombosis and Haemostasis, be charged with ensuring the orderly assignment of new HPA designations after confirmation of the alloantibody reactivity and specificity. A list of HPA assignments based on the 2002 platelet workshop describes 16 HPA systems and antigens (Table 20.9). Some alloantibodies have been reported that recognize only the low-frequency antigens at certain loci, mainly on gpIIIa. Thus, their HPA designations are not considered at present to be true antigen systems, because there is, as yet, no evidence that the antithetical high-frequency polymorphism induces structural changes that would be immunogenic in an individual homozygous for the low-frequency allele. Only HPA-1 through HPA-5 and HPA-15 alloantigens constitute complete systems in which alloantibodies to both alleles have been reported.

The HPA system is useful when considering the alloimmune thrombocytopenias, especially for the simple identification of the relevant pathologic alloantibody and the zygosity of the patient for that allele. However, it should be noted that the HPA system is misleading from a genetic point of view.²⁰⁶ Many polymorphisms evolved at different loci on the PL^{A1} variant of the gpIIIa gene. Thus, there are two HPA designations (i.e., HPA-1a and HPA-4a) for the single gpIIIa gene encoding Leu33 and Arg143. Furthermore, Newman noted that if alloantibodies were found to all the high-frequency alleles on gpIIIa, then the designations PL^{A1}, Pen^a, Mo^b, Ca^b, and Sr^b all would refer to the same molecular entity. However, although a description of the gene by its haplotype would be of benefit when considering the concept that combinations of polymorphisms could have different effects on protein function, at present, there is no nomenclature that can efficiently describe haplotypes.

Platelet-specific Alloantigens: Biochemistry and Genetics

Glycoprotein IIb/IIIa (αIIbβ3)

Glycoproteins IIb and IIIa form a heterodimer complex that is a member of the integrin family of integral membrane proteins, a superfamily of noncovalently associated α and β subunits involved in cell-cell and cell-vessel contact. Of these, gpIIb/IIIa, with 50,000 to 80,000 surface copies, is expressed most abundantly by far on platelets.²⁰⁷ Activated gpIIb/IIIa mediates platelet aggregation through binding to fibrinogen and VWF. A complex of the α and β subunits is required for expression of the gpIIb and gpIIIa subunits on the surface. A deficiency of gpIIb/IIIa results in Glanzmann thrombasthenia, an inherited bleeding disorder.^{208,209} The gene for gpIIIa, located on chromosome 17, may be the most polymorphic of the human integrin subunits.^{210,211,212,213} and ²¹⁴ Hence, a large number of platelet alloantigens, including HPA-1 (PL^A), HPA-4 (Pen), HPA-6 (Ca/Tu), HPA-7 (Mo), HPA-8 (Sr), HPA-10 (La), HPA-11 (Gro), HPA-14 (Oe), and HPA-16 (Duv) determinants, are located on gpIIIa. Polymorphisms of the gene on chromosome 17 encoding the α subunit, gpIIb, are responsible for the HPA-3 (Bak) and HPA-9 (Max) alloantigens. Glycoprotein IIb is synthesized exclusively by megakaryocytes; thus,

gpIIb/IIIa is unique to platelets. However, the gpIIIa subunit also is expressed on endothelial cells in association with the subunit αv to form the vitronectin receptor, also expressed in low numbers on the platelet surface.

Glycoprotein Ia/IIa ($\alpha 2\beta 1$)

The collagen receptor, gplIa/IIa, is a member of the integrin family of cell surface receptors. These membrane glycoprotein heterodimers consist of noncovalently associated α and β subunits.^{68,215,216,217} and ²¹⁸ Patients in whom deficiencies of gplIa/IIa are reported demonstrate chronic mucocutaneous bleeding associated with prolonged bleeding times.^{219,220} Three or more alleles of the $\alpha 2$ gene regulate the level of expression of gplIa/IIa on platelets.^{221,222} and ²²³ Quantitative binding of platelets to type I or III collagens correlates with the number of gplIa/IIa molecules expressed on the platelet surface.²²² Alloantibodies to the HPA-5 (Br/Zav) and HPA-13 (Sit) determinants are expressed on gplIa.

P.532

FIGURE 20.4 Schematic representation of amino acid substitutions that determine human platelet antigens (HPAs). The relative locations of the various amino acid substitutions encoded by single nucleotide polymorphisms are indicated on the respective platelet glycoprotein (GP). One antigen (HPA-14bw) results from an in-frame deletion of three nucleotides on the HPA-1b allele of the β -IIIa (ITGB3) gene. Immunization to the alloantigens determined by the highly polymorphic gene for GPIIIa accounts for the majority of clinically significant alloimmune thrombocytopenias.

Glycoprotein CD109

CD109 is a monomeric 175-kD glycoprotein that is anchored to the platelet membrane by glycosylphosphatidyl-inositol (GPI).²²⁴ The precise function for the GPI-anchored protein is not known. However, the recent determination of the cDNA

sequence for CD109 indicates that it is a novel member of the $\alpha 2M/C3, C4, C5$ family of thioester-containing proteins and thus may mediate covalent cell-substrate and cell-cell interactions.²²⁵ Although CD109 expression has been reported to be activation dependent on platelets, this has not been established. It is possible that the protein is constitutively expressed on the resting platelet and undergoes structural changes after activation that expose epitopes for certain monoclonal antibodies.^{224,226,227} The HPA-15 (Gov) alloantigens are expressed on CD109.^{224,226}

HPA, human platelet antigen.

Glycoprotein Ib/IX/V

Glycoprotein Ib consists of two disulfide-linked proteins (gplbα and gplbβ) and is found on the platelet surface in association with gplX and gpV.²²⁸ The four polypeptides share similar structural features, including a region of leucine-rich repeats, and are encoded by four separate genes. The short arm of chromosome 22 contains the gene for gplbα; the long arm contains the gene for gplbβ.^{229,230} The genes for gplX and gpV are located on chromosome 3.²³¹ The gplb-IX-V complex resides on the platelet surface as a heptamer, with one molecule of gpV flanked by two molecules each of gplX, gplbα, and gplbβ.^{228,232} A region within the amino-terminal domain of gplbα functions as the major receptor for VWF, which mediates platelet contact and adhesion to damaged endothelium.^{233,234} and ²³⁵ A deficiency or lack of gplb-IX-V is associated with the Bernard-Soulier syndrome, an inherited bleeding disorder.^{236,237} and ²³⁸ Platelets express approximately 25,000 copies of the gplb-IX-V complex.²³⁹ Alloantibodies have been reported that recognize the HPA-2 (Ko) and HPA-12 (Iy) determinants on gplbα and gplbβ, respectively.

Clinically Significant Platelet Alloantigens

HPA-1: PI^A Polymorphism

SUMMARY: HPA-1 ANTIGENS

Antibody Specificity	Clinically Significant	NAT	PTP	PAT	PTR	TAT	Comments
HPA-1a	Yes	Yes	Yes	Yes	Yes	Yes	Associated with severe thrombocytopenia
HPA-1b	Seldom	Yes	Yes	No	Yes	No	

HPA, human platelet antigen; NAT, neonatal alloimmune thrombocytopenia; PAT, passive alloimmune thrombocytopenia; PTP, posttransfusion purpura; PTR, posttransfusion refractoriness; TAT, transplantation-associated thrombocytopenia.

The HPA-1a/1b alloantigen system has been associated with all of the alloimmune thrombocytopenic syndromes P.534

and is the primary cause of NAT and PTP in whites.²⁴⁰ Alloimmunization to the HPA-1 antigens is important both for the frequency (>75%) and for the severity of thrombocytopenia, which often is greater for syndromes involving the gplIb/IIIa complex.³⁰ A Leu (HPA-1a) to Pro (HPA-1b) change at residue 33 is encoded by a T to C substitution at position 196 of gpIIIa (ITGB3) cDNA.²⁴¹ The gene frequencies in the white population are 0.85 and 0.15 for HPA-1a and HPA-1b, respectively. A third allele for the HPA-1 system has recently been reported.²⁴² A naturally occurring Leu33Val change resulting from a C to G change at position 175 on the ITGB3 gene was shown to affect the binding of some anti-PL^{A1} antisera. The mutation occurs 5' to the polymorphism at position 176 encoding the HPA-1 antigens and therefore it is likely that current genotyping methods will incorrectly identify the Val33 β3 gene as encoding the Leu33 form of the protein. It is possible that the frequency of this polymorphism is higher than the 2 per 2,951 individuals reported.²⁴² A second substitution, Leu to Arg at residue 40, of <3% of HPA-1b alleles, has no known clinical significance.^{243,244}

Alloimmunization to HPA-1a is associated with the immune response genes HLA-DRB3*0101 or -DQB1*0201. Heterogeneity in the binding of anti-HPA-1a antibodies to platelets may be a consequence of a complex and disulfide-bonded structure in the amino-terminal portion of gpIIIa that imposes a threedimensional structural constraint on the HPA-1a antigen.^{245,246,247} and ²⁴⁸ Further evidence for structural factors distant to the Leu33Pro substitution in the control over the expression of the HPA-1a epitope was recently reported in 1 of 6,000 individuals tested for antigen status using phenotyping and genotyping. An Arg93Gln substitution on the Leu33 allele disrupted the formation of the HPA-1a antigen

phenotype in an individual who had been typed positive for PL^{A1} using genotyping.²⁴⁹ Alloantibodies to PL^{A1} inhibit clot retraction and platelet aggregation, possibly by blocking fibrinogen binding.^{250,251}

HPA-5: Br/Zav Polymorphism

SUMMARY: HPA-5 ANTIGENS

Antibody Specificity	Clinically Significant	NAT	PTP	PAT	PTR	TAT	Comments
HPA-5a	Yes	Yes	Yes	No	Yes	No	Usually causes moderate thrombocytopenia
HPA-5b	Yes	Yes	Yes	Yes	Yes	Yes	

HPA, human platelet antigen; NAT, neonatal alloimmune thrombocytopenia; PAT, passive alloimmune thrombocytopenia; PTP, posttransfusion purpura; PTR, posttransfusion refractoriness; TAT, transplantation-associated thrombocytopenia.

The HPA-5a/5b alloantigens have been associated with all of the alloimmune thrombocytopenic syndromes and are the second most common cause of NAT in whites.²⁴⁰ A Glu (HPA-5a) to Lys (HPA-5b) change at residue 505 is encoded by a G to A substitution at position 1648 of gplα (MMRN1) cDNA.²⁵² The frequencies in the white population are 0.89 and 0.11 for HPA-5a and HPA-5b, respectively. The HPA-5b allele is in linkage disequilibrium with the -52T polymorphism associated with lower levels of surface gplαIIa.^{221,222} However, platelets from HPA-5aa and HPA-5bb homozygous donors do not demonstrate differences in their static adhesion to collagen.²⁵²

HPA-15: Gov Polymorphism

SUMMARY: HPA-15 ANTIGENS

Antibody Specificity	Clinically Significant	NAT	PTP	PAT	PTR	TAT	Comments
HPA-15a	Yes	Yes	No	No	Yes	No	Usually causes moderate thrombocytopenia
HPA-15b	Yes	Yes	?	No	Yes	No	

HPA, human platelet antigen; NAT, neonatal alloimmune thrombocytopenia; PAT, passive alloimmune thrombocytopenia; PTP, posttransfusion purpura; PTR, posttransfusion refractoriness; TAT, transplantation-associated thrombocytopenia.

The HPA-15a/15b (Gov^{a/b}) alloantigens have been associated with NAT, PTP, and PTR.^{224,226,253} Large studies on the frequency of the HPA-15 alloantibodies have recently been made possible by the adaptation of the monoclonal antibody immobilization of platelet antigens (MAIPA) technology to include monoclonal capture antibodies for CD109. These studies indicate that immunization to the HPA-15a/15b alloantigens is second only to the HPA-1a antigen, occurring as often as HPA-5a/5b antibodies.²⁵⁴ The HPA-15a/15b antigens are the result of a Ser (HPA-15a) to Tyr (HPA-15b) change at residue 703 encoded by a C to A substitution at position 2108 of CD109 cDNA.²⁵⁵ Large European studies indicate that the frequencies for the HPA-15a and -15b antigens are 0.59 and 0.41, respectively. The HPA-15a/15b alloantigens are unique because they can be removed from the platelet surface by the action of phospholipase on the membrane anchor.²²⁴

HPA-3: Bak Polymorphism

SUMMARY: HPA-3 ANTIGENS

Antibody Specificity	Clinically Significant	NAT	PTP	PAT	PTR	TAT	Comments
HPA-3a	Yes	Yes	Yes	No	No	No	Can cause severe thrombocytopenia
HPA-3b	Seldom	?	Yes	No	Yes	No	

HPA, human platelet antigen; NAT, neonatal alloimmune thrombocytopenia; PAT, passive

alloimmune thrombocytopenia; PTP, posttransfusion purpura; PTR, posttransfusion refractoriness; TAT, transplantation-associated thrombocytopenia. The HPA-3a/3b (Bak^{a/b}, Lek^a) alloantigens have been associated with NAT and PTP. Although less common, HPA-3a antibodies can occasionally cause thrombocytopenia as severe as the HPA-1a mediated disease. An Ile (HPA-3a) to Ser (HPA-3b) change at residue 843 is encoded by a T to G substitution at position 2622 of gpIIb (*ITGA2B*) cDNA,²⁵⁶ creating the HPA-3 epitopes on the heavy chain of the integrin subunit. The frequencies in the white population are 0.61 and 0.39 for HPA-3a and HPA-3b, respectively. Unlike other platelet-specific alloantigens, posttranslational glycosylation modifications may contribute to the expression of the HPA-3a/3b epitopes.^{256,257 and 258}

P.535

HPA-2: Ko Polymorphism

SUMMARY: HPA-2 ANTIGENS

Antibody Specificity	Clinically Significant	NAT	PTP	PAT	PTR	TAT	Comments
HPA-2a	Yes	?	No	No	?	No	Usually causes moderate thrombocytopenia
HPA-2b	Yes	Yes	No	No	Yes	No	

HPA, human platelet antigen; NAT, neonatal alloimmune thrombocytopenia; PAT, passive alloimmune thrombocytopenia; PTP, posttransfusion purpura; PTR, posttransfusion refractoriness; TAT, transplantation-associated thrombocytopenia.

The HPA-2a/2b (Ko^{a/b}) antigens have been associated with NAT and PTR and are expressed on gplb α .^{259,260,261,262} and ²⁶³ A Thr HPA-2a to Met HPA-2b change at residue 145 is encoded by a G to A substitution at position 524 of gplb α (GP1BA) cDNA. The frequencies in the white population are 0.911 and 0.089 for HPA-2a and HPA-2b, respectively.²⁶¹ Some evidence has been reported that shows anti-HPA-2 alloantibodies prevent ristocetin-induced agglutination²⁶¹; however, this has not been confirmed in other studies.^{264,265} The HPA-2 antigens may be in linkage disequilibrium with a variable number of tandem repeat (VNTR) polymorphism that is responsible for four different molecular weights for the gplb α molecule. A tandem of 13 amino acids in the mucin-rich domain can be expressed with one to four repeats, thus encoding polypeptides of different lengths (VNTR-A, -B, -C, and -D alleles have 4, 3, 2, and 1 repeats, respectively).²⁶⁶ The HPA-2b allele may have originated on the VNTR-B allele, from which the VNTR-A allele was derived. Because <1,000 base pairs separate the HPA-2 and VNTR loci, the rate of cross-over during meiosis would be low, and, in most populations, the HPA-2b antigen is expressed on the VNTR-A and -B alleles.^{260,267} However, there is evidence that crossover may have occurred.²⁶⁸

HPA-4: Pen Polymorphism

SUMMARY: HPA-4 ANTIGENS

Antibody Specificity	Clinically Significant	NAT	PTP	PAT	PTR	TAT	Comments
HPA-4a	Yes ^a	Yes	Yes	No	No	No	Usually causes moderate thrombocytopenia
HPA-4b	Yes ^a	Yes	No	No	No	No	

HPA, human platelet antigen; NAT, neonatal alloimmune thrombocytopenia; PAT, passive alloimmune thrombocytopenia; PTP, posttransfusion purpura; PTR, posttransfusion refractoriness; TAT, transplantation-associated thrombocytopenia.

^a Anti+HPA-4 alloantibodies are important in the Asian population due to the higher frequency of the

HPA-4b allele.

The HPA-4a/4b (Pen^{a/b} /Yuk^{b/a}) alloantigens have been associated with NAT and PTP. An Arg (HPA-4a) to Gln (HPA-4b) change at residue 143 is encoded by a G to A substitution at position 525 of gpIIIa (ITGB3) cDNA.²⁶⁹ Because the frequencies in the white population are >0.99 and <0.01 for HPA-4a and HPA-4b, respectively, this alloantigen system is of little consequence clinically in North America and Europe. However, HPA-4b is expressed in approximately 1% of Asians and contributes significantly to platelet alloimmunization. Anti-HPA-4a antibodies can inhibit platelet aggregation, consistent with the proximity of the epitope to the RGD-binding domain.²⁵⁰

Low-frequency Antigens

It is now clear that immunization to low-frequency polymorphisms is more common than previously thought. These antigens have been identified following detection of antibody in the maternal serum that reacts only to determinants on the paternal platelets. In some cases the antigen has been found in a few other individuals in the general population. However, the vast majority of cases referred for NAT testing that test negative for antibodies to the common antigens cannot be explained by incompatibility for low-frequency alleles.²⁷⁰ Genetic variations of the ITGA2B (gpIIb) and ITGB3 (gpIIIa) genes that entered the human genome after the HPA-1a/1b and HPA-3a/3b polymorphisms have been reported in association with alloimmunization causing NAT. For example, HPA-9bw (Max^a) antigen is found only in individuals carrying the HPA-3b (Bak^b) form of the ITGA2B gene.²⁷¹ The majority of the low-frequency antigens on gpIIIa have occurred as mutations on the Leu33 form of the ITGB3 gene. Of interest, a second immunogenic polymorphism (Hit^a) has been identified that results in a third allele of HPA-7w.²⁷² Until alloimmunization to the antithetical antigen is demonstrated in an individual homozygous for the low-frequency antigen, these polymorphisms are not considered true alloantigen systems within the HPA nomenclature. Table 20.10 summarizes the low-frequency polymorphisms identified to date.

Other Platelet Antigens

The Nak^a antibody originally was reported in a multitransfused Japanese patient.^{272a} The antibody bound to gpIV on approximately 90% of donor platelets. However, further studies demonstrated that individuals who formed the anti-Nak^a antibodies actually lacked gpIV on their platelets.^{273,274} The antibody bound to epitopes on gpIV that were not encoded

P.536

by polymorphisms; thus, anti-Nak^a is more correctly called an isoantibody, similar to the anti-gpIIb/IIIa antibodies induced in transfused individuals who lack gpIIb/IIIa on their platelets (Glanzmann thrombasthenia).

Alloantigens Not Specific to Platelets

Alloantigens that are not restricted to the megakaryocyte lineage can also be expressed on platelets. These include the ABH blood determinants and MHC class I molecules.

ABH Blood Group Antigens

It is now known that most of the membrane proteins on the surface of platelets can express determinants of the ABH blood groups. These include the gplb/IX/V, gpIib/IIIa, gpIV, gpV, CD31, and CD109 molecules.^{275,276} and ²⁷⁷ Approximately 25% of platelets mismatched for the A or B blood groups are immediately cleared when transfused to an incompatible recipient. The remaining ABO-incompatible platelets have a normal survival, possibly explained by the platelet-to-platelet variability in the number of A and B antigens.^{278,279} and ²⁸⁰

Human Leukocyte Antigens

The class I HLAs are expressed on the surface of platelets. These highly polymorphic antigens are the major cause of refractoriness to platelet transfusion. In contrast to the relatively constant numbers of molecules on lymphocytes, the level of expression of the HLA molecule on platelets can vary markedly (up to 35-fold) among different individuals.^{281,282} Because the HLA-C antigen levels are very low on platelets, only the HLA-A and -B antigens are a consideration when cross-matching for transfusion.²⁸³ Although a number of reports suggest that HLA antigens can play a role in causing NAT, other studies indicate that HLA antibodies may be innocent bystanders and would not play a role in fetal/neonatal thrombocytopenia.^{284,285,286} and ²⁸⁷

Alloimmune Thrombocytopenic Disorders

Platelet-specific alloantibodies play a major role in the immunopathology and thrombocytopenia observed in NAT and PTP. Alloantibodies also mediate platelet clearance in two less common syndromes: PAT and TAT. In addition, antiplatelet antibodies may play a role in refractoriness to platelet transfusions. However, more commonly in these patients, the thrombocytopenia is complicated by septicemia or by HLA antibodies.

Neonatal Alloimmune Thrombocytopenia

NAT is caused by maternal IgG alloantibodies that cross the placenta and cause the destruction of fetal platelets. Maternal alloimmunization to paternally derived alloantigens on the fetal platelets can occur early, often within the first trimester of the first pregnancy. Although analogous to HDN, alloimmunization to inherited paternal platelet antigens and the destruction of fetal platelets can occur during the first pregnancy with an antigenincompatible fetus. Thus, NAT often presents as unexpected isolated severe thrombocytopenia in an otherwise healthy neonate. Thrombocytopenia can be severe, with the platelet count falling to $<10 \times 10^9/L$ within the first few days after birth, and may take several weeks to return to normal. Clinical findings include petechiae in 90%; gastrointestinal tract hemorrhage in 30%; and hemoptysis, hematuria, and retinal bleeding in $<10\%$ of patients. Intracranial hemorrhage is found in 10% to 20% of neonates and can occur early during pregnancy. Hydrocephalus, porencephalic cysts, and epilepsy can complicate recovery from fetal and neonatal intracranial bleeding. Anemia and hyperbilirubinemia can occur from extravasation and resorption of blood.

Although more than 23 different platelet alloantigen systems have been described, most cases of NAT are caused by alloantibodies to HPA-1a (PL^{A1}, Zw^a) (78%), HPA-5b (Br^a, Zav^a), and HPA-15b (Gov^a). Recent evidence suggests that alloimmunization to HPA-15 antigens in NAT can occur more often than thought previously and can be as frequent as immunization to HPA-5 antigens. Other alloantigens implicated in NAT include HPA-1b, HPA-2b, HPA-3a, HPA-3b, HPA-4a, HPA-4b, HPA-5a, and HPA-15a. However, it is now clear that immunization to "private" alloantigens also can cause NAT. The majority of these have been found as rare polymorphisms on paternal $\beta 3$ (ITGB3). The mother carries the common

form of the gene and becomes immunized to alloantigens expressed only on the fetal platelets and on those from the father and his immediate family (e.g., HPA-8bw). In some cases, a polymorphism has also been detected in a few unrelated individuals in the general population and is termed a low-frequency antigen (e.g., HPA-6bw). These rare alloantigens have been, to date, reported only in NAT, which requires only one exposure to paternal alloantigens during pregnancy. This is in contrast to the other classic alloimmune syndrome, PTP, which is associated with two temporally distinct exposures to the immunizing antigen. The PTP patient is usually immunized initially via pregnancy and is later re-exposed via transfusion. This requirement for two exposure events would exclude the rare platelet alloantigens from a role in PTP. However, it is possible that a selection bias could eventually increase the relative frequency of the rare antigens in the general population and allow for their participation in PTP and other transfusion and transplantation-mediated alloimmune disorders. In theory, directed donations of blood, organs, or bone marrow to family members could cause alloimmunization involving a rare alloantigen. It is now apparent that the low-frequency alloantigen HPA-9bw (Max³) may be implicated more frequently in some cases of severe thrombocytopenia and intracranial hemorrhage than was previously suggested. Two recent reports indicate that immunization to HPA-9bw is not uncommon and can account for up to 2% of confirmed cases of NAT.^{288,289}

In large studies, antibodies to HPA-1a are found in the majority (78%) of serologically confirmed cases of NAT, with antibodies to HPA-5a and -5b and HPA-15a and -15b antigens identified in approximately 20%. All other specificities account for the remaining small percentage of alloantibodies found. However, up to 60% of clinically identified cases of NAT lack serologic evidence of antiplatelet alloantibodies.²⁴⁰ In some cases, a portion of clinically identified NAT may be reported "antibody-negative," possibly due to a lack of assay sensitivity or specificity. The first report of platelet alloantibodies in 1969 was followed by almost 20 years in which only three additional alloantibody specificities were detected using then-current methodology, including the platelet suspension immunofluorescence test and direct binding enzyme immunoassays. When the use of glycoprotein-specific assays for antiplatelet antibody studies became established, the rate of detection of new alloantibodies and antigens increased significantly.³⁰ By measuring the binding of maternal IgG to specific platelet glycoproteins, the MAIPA and radioimmunoprecipitation assays are able to detect specific antiplatelet alloantibodies binding to proteins expressed in low numbers on the platelet surface (e.g., I₁a) and discriminate this from background binding of IgG to non-platelet-specific epitopes (e.g., anti-HLA). Although the sensitive and specific MAIPA assay is used widely in reference laboratories to screen for alloantibodies, it too is limited by the requirement for specific monoclonal antibodies to various platelet glycoproteins to detect antiplatelet antibodies. Thus, some clinical NAT cases may not be corroborated with a positive laboratory test for alloantibodies because the maternal immunization is directed against epitopes on platelet proteins to which monoclonal antibodies are unavailable. This was demonstrated by the report of alloimmunization to epitopes on a novel platelet

P.537

protein, CD109. Although no alloantibodies were detected using the routine MAIPA assay with capture monoclonal antibodies to glycoproteins Ia/IIa, Ib/IX, and IIb/IIIa, anti-Gov^{a/b} (HPA-15a/15b) reactivity was readily identified using radioimmunoprecipitation. Until monoclonal antibodies to CD109 are used routinely in the MAIPA, the radioimmunoprecipitation assay may be used to detect HPA-15 alloantibodies. The enhanced sensitivity imparted by radiolabeling the majority of platelet proteins, including those expressed in low numbers on the platelet surface, has established the radioimmunoprecipitation assay as a universal screening method for platelet alloantibodies in NAT.

NAT is estimated to occur in 1 in 1,000 to 2,500 births. The alloantibodies most often involved are directed against HPA-1a. Because the HPA-1b/1b (PL^{A1}-negative) phenotype is found in approximately 2% of the North American population, the theoretical risk for NAT in newborns is approximately 1 in 50 births, which is much higher than observed cases. Although it is possible that limitations in recognition and technical issues in testing for alloantibodies might play a role in the underdiagnosis of some cases of NAT, the lower-than-expected responsiveness to the HPA-1a antigen in susceptible women demonstrates that additional factors play a role in alloimmunization.²⁹⁰ Maternal immunization to HPA-1a shows an HLA restriction, wherein HPA-1b/1b women who produce alloantibodies are almost exclusively HLA-DRB3*0101 or -DQB1*0201. The risk factor in the case of -DQB1*0201 is 141, similar to that for the HLA-B27 restriction in the autoimmune disease ankylosing spondylitis.²⁹¹ In one case of NAT, T cells were shown to play a role in the HLA restriction. Peptides that contain the same Leu33 polymorphism that is recognized by anti-HPA-1a antibodies were able to stimulate T cells sharing CDR3 motifs.²⁹² However, alloimmunization to the HPA-1b (PL^{A2}) antigen is not associated with a specific HLA type and has a much lower incidence in NAT.^{293,294} This may explain the observation that although phenotype frequencies for HPA-1a and HPA-1b predict that anti-HPA-1b should be observed six times more frequently than anti-HPA-1a, alloimmunization to HPA-1a accounts for far more cases of NAT than anti-HPA-1b.³⁰ In a large study of clinically suspected

NAT, alloantibodies to HPA-1a were found more frequently by a ratio >100:1 when compared with anti-HPA-1b.²⁴⁰ Another risk factor may involve blood group antigens. In one report, severe NAT due to HPA-1a immunization was associated with maternal ABO genotypes, with group A mothers having a higher risk of giving birth to children with severe thrombocytopenia, possibly due to genetic linkage.²⁹⁵ Immunization to the HPA-5a/5b alloantigens also has been associated with specific class II genes.^{296,297} However, unlike the reversed relative risk versus the expected rates of immunization reported for the HPA-1a/1b system, the theoretical ratio of alloimmunization against HPA-5a versus HPA-5b is similar to the observed ratio.^{30,298}

The differences in the rate of immunization to platelet alloantigens also vary between different racial or ethnic populations. The distribution and frequency of platelet alloantigen genes in the worldwide population is a major factor in determining which alloantigens are most important in the investigation of NAT in different countries (Table 20.11). Although studies have shown that the HPA-1a antigen accounts for the majority of NAT cases in the white population, it has rarely been shown to play a role in the Japanese. This may be explained by the lower frequency for HPA-1b in the Japanese population compared with whites (0.02 vs. 0.15). Without accounting for differences in the frequency of immune response genes, alloimmunization to HPA-1a should be at least 50 times less in the Japanese population. Antibodies to HPA-4a/4b are most frequently reported in Japanese cases of alloimmunization. This may be related directly to the higher frequency for HPA-4b in the Japanese population compared with whites (0.0083 vs. <0.001), which would increase the number of individuals homozygous for the rare allele who would then be at risk for alloimmunization to HPA-4a.

TABLE 20.11 HUMAN PLATELET ANTIGEN (HPA) FREQUENCY BY ETHNIC GROUP

Antigen	Gene Frequency			References
	White	Black	Asian	
HPA-1a	0.85-0.89	0.92	0.99-1.00	242,425,426,427,428 and 429
HPA-1b	0.11-0.15	0.08	0.00-0.01

Immunization to platelet nonspecific alloantigens such as ABO and HLA is more likely to play a role in transfusion- and transplantation-associated thrombocytopenia rather than NAT. As these antibodies pass from the mother into the fetal circulation, they are likely to be targeted to the larger population of HLA- and ABO-bearing cells rather than to platelets. In cases in which only ABO or HLA antibodies are observed in NAT, it is possible that platelet-specific alloantibodies are present but go undetected due to the technical limitations of current assays.

Diagnostic tests for NAT should be designed to determine the maternal and paternal platelet alloantigen haplotypes to assess the presence of antigen incompatibilities. Genotyping should be used to determine the alloantigen status because few laboratories have adequate typing sera available to perform immunophenotyping for all the relevant alloantigens. Because genotyping uses very little sample, it also allows for the determination of fetal platelet antigens directly, rather than inferring them from the paternal platelet typing. To detect platelet-specific alloantibodies in maternal serum, a specific and sensitive assay should be used that can discriminate the presence of coexisting platelet nonspecific antibodies (e.g., anti-HLA). Due to the possibility of maternal alloimmunization to relatively low-frequency alloantigens, including HPA-5b, it is preferable to test for antiplatelet antibodies using the father's platelets as a target. Although it is important to assess the risk for NAT in future pregnancies, this can be complicated by the presence of both alleles in a heterozygous father. In such cases, the fetal platelet alloantigens can be determined by genotyping fetal amniocytes obtained between 16 and 20 weeks' gestation. Although the presence of high-titer anti-HPA-1a is associated with severe neonatal thrombocytopenia when tested before 28 weeks' gestation, fetal/neonatal morbidity and severe thrombocytopenia have been observed when no antiplatelet antibody can be detected. Therapy with intravenous γ -globulin also can reduce

antibody levels in women who still deliver severely affected children, making it difficult to predict severity of thrombocytopenia based on antibody titer.²⁹⁹

Posttransfusion Purpura

PTP typically presents as severe thrombocytopenia resulting within 7 to 10 days after an immunogenic blood transfusion. It usually affects elderly women who have been sensitized to the platelet alloantigen during a previous pregnancy.^{30,300}

Because prior transfusion also has been reported as the initial immunizing event, occasionally males can develop PTP. As in NAT, the most common alloantibody implicated in PTP is directed against

P.538

HPA-1a and follows transfusion of antigen-positive blood to HPA-1b/1b/HLA-DR3-positive individuals. The frequency of PTP has decreased significantly in recent years, likely as a result of routine pre-storage leukoreduction in certain countries.³⁰¹

Thrombocytopenia can result from the transfusion of any blood product—not only platelets—and is most commonly seen after the infusion of packed red cells. Fever and chills are often observed during the transfusion; this is followed by petechiae and ecchymoses once thrombocytopenia develops. It is important to recognize this rare disorder because the severe thrombocytopenia can cause mucosal surface bleeding and subsequent anemia, with fatal intracranial hemorrhage observed in approximately 10% of patients. Therapy using high-dose intravenous γ -globulin has been shown to be effective and may be augmented with transfusion of antigen-negative platelets. Because PTP often presents in postoperative patients, the differential diagnosis of PTP includes other common thrombocytopenic syndromes such as heparin-induced thrombocytopenia and bacteremia. However, unlike PTP, these other disorders do not commonly present with severe thrombocytopenia ($<10 \times 10^9/L$). In addition, heparin-induced thrombocytopenia is often associated with thrombotic complications rather than the overt bleeding that characterizes PTP.

The major challenge of PTP is to understand the mechanism underlying the destruction of autologous platelets that follows the exposure and sensitization to immunizing blood product. A number of theories have been proposed to explain the clearance of the antigen-negative (HPA-1b/1b) platelets in the presence of anti-HPA-1a antibodies. The mechanisms proposed include the adsorption of alloantigen-alloantibody immune complexes to receptors on recipient platelets with subsequent clearance mediated by complement or by the reticuloendothelial system (innocent bystander syndrome); the binding to autologous platelets of soluble or microparticle-associated alloantigen derived from the destruction of transfused blood product, thus making the recipient platelets a target for the alloantibodies; or, finally, the presence of pseudospecific alloantibodies that are produced in the early phase of the anamnestic response and can bind to determinants on autologous platelets, leading to their destruction.^{30,300} This is supported by evidence that anti-HPA-1a antibodies from patients with PTP not only have a higher titer than NAT, but also react to a broader, more complex epitope.²⁴²

As in NAT, platelet typing and antiplatelet antibody testing are necessary to identify the pathogenic alloantibodies. However, because of the severe thrombocytopenia in the acute stages of PTP, genotyping is required to assess the risk for alloimmunization. Although anti-HPA-1a is most often implicated, PTP also is reported in association with alloimmunization to other platelet-specific antigens, including HPA-1b, HPA-3a/3b, HPA-4a, HPA-5a/5b, HPA-2b, and HPA-15b. Some of these antigens are distributed with relatively low frequencies in the population, and screening for antiplatelet antibodies should therefore use sensitive and specific assays and an informative panel of target platelets.

Passive Alloimmune Thrombocytopenia

The abrupt onset of thrombocytopenia within a few hours after transfusion of a blood product is a hallmark of PAT. Platelet-specific alloantibodies in the blood product (usually plasma) rapidly clear the recipient's antigen-positive platelets. This syndrome manifests within hours of transfusion and has a shorter duration of thrombocytopenia than PTP, mediated by the amount and specificity of the transfused alloantibody. Testing for PAT has shown that it is difficult to measure alloantibody in the recipient's plasma, suggesting that the transfused antibodies are limited and bind to the incompatible platelets soon after transfusion. However, the alloantibody can be detected in the donor plasma, and in one case, sensitization of recipient platelets by the transfused alloantibody *in vivo* was demonstrated using direct radioimmunoprecipitation to measure IgG bound to platelet gpIIb/IIIa directly on the patient's platelets.³⁰² Alloantibodies against the HPA-1a and HPA-5b antigens have been implicated in passive alloimmune thrombocytopenia.^{30,300} Severe thrombocytopenia is found in association with the transfusion of blood products containing alloantibodies to the HPA-1a antigen. The finding that even red blood cell concentrates can cause PAT due to anti-HPA-1a antibodies correlates with reports that as little as 10 ml of plasma containing alloantibodies can cause thrombocytopenia in transfused volunteers.³⁰³

Because thrombocytopenia can occur in multiple transfusion recipients, it is important to investigate cases of suspect PAT to ensure that the alloimmunized blood donor does not donate blood in the future.³⁰⁴

Transplantation-associated Alloimmune Thrombocytopenia

Alloimmune mechanisms can explain the rare syndrome of transplantation-associated alloimmune thrombocytopenia that can complicate transplantation either with a solid organ or with allogeneic bone marrow.³⁰ Both anti-HPA-1a and anti-HPA-5b alloantibodies can cause thrombocytopenia that may develop very soon or sometimes longer after transplantation. In one case, a man with Ph1 chromosome-positive chronic myelogenous leukemia developed severe thrombocytopenia ($17 \times 10^9/L$) 18 months after receiving an allogeneic bone marrow transplant from his HLA-matched sister.³⁰⁵ An immune mechanism was suggested by the repeated platelet count increase after treatment with high-dose intravenous γ -globulin and remission after splenectomy. Anti-HPA-1a antibodies were detected in Ig eluted from the patient's platelets. Although chromosome analysis of the patient's marrow demonstrated a normal Ph1-negative female karyotype, sensitive Southern blot analysis of splenic cell DNA identified a small amount (3%) of residual male cells. The patient's sister was HPA-1a positive, and another brother was HPA-1a negative. Although pretransplant platelet alloantigen studies were not done, it was deduced that the patient was likely HPA-1a negative (HPA-1b/1b) and that the thrombocytopenia was mediated by a host versus donor alloimmune thrombocytopenia in which the patient's residual lymphoid cells developed an anti-HPA-1a alloimmune response to HPA-1a-positive platelets derived from the engrafted bone marrow.

Alloimmune-mediated platelet destruction due to a bone marrow transplant recipient's pre-existing anti-HPA-5b antibodies was suggested by a rapid transient increase in platelet count from 43 to $108 \times 10^9/L$ after administration of intravenous γ -globulins.³⁰⁶ The patient received the allogeneic marrow from her HLA-matched brother who typed positive for HPA-5b. The detection of a small amount (<5%) of group A blood cells in the recipient after transplantation with her brother's group O marrow indicated that a chimeric state existed in this patient. The thrombocytopenia eventually improved as the level of circulating antibody decreased.

Thrombocytopenia that may also have an alloimmune mechanism was reported in patients after autologous peripheral blood stem cell transplantation for metastatic breast carcinoma.³⁰⁷ Both patients had pre-existing anti-HPA-1a antibodies that rose in titer after transplantation. Because moderate to severe thrombocytopenia is expected soon after transplantation due to marrow ablative treatment, variable rate of engraftment of donor marrow-derived megakaryocyte precursors, and fever and other comorbid clinical factors, it is difficult to determine the pathogenic mechanism in these patients. Although the thrombocytopenia may have resulted from a refractory state caused by the rapid clearance of transfused platelets by alloantibodies, it is also possible that platelets derived from engrafted autologous marrow were destroyed in a PTP-like syndrome.

P.539

Solid organ transplants rarely can lead to alloimmune thrombocytopenia. Donor-derived immunocompetent lymphoid cells contained within the organs transplanted from a single donor to three recipients (two kidneys, one liver) are suspected to be the cause of severe thrombocytopenia (platelet count nadirs: 2, 2, and $12 \times 10^9/L$) that developed within 5 to 8 days.³⁰⁸ The severe thrombocytopenia in the renal transplant patients was refractory to intravenous γ -globulins and platelet transfusions. One patient recovered after splenectomy 50 days after transplantation, and the other died due to multiorgan failure associated with bacteremia and severe thrombocytopenia. The thrombocytopenia resolved in the liver transplant recipient after receiving a new liver following rejection of the first transplant. Serum from the multiparous female organ donor was shown to contain anti-HPA-1a alloantibodies. Platelet typing and antibody studies of the transplant recipients showed that although they typed HPA-1a positive, anti-HPA-1a antibodies were detected in their posttransplant, but not pretransplant, sera. These observations suggest that anti-HPA-1a antibodies derived from transplanted immunocompetent lymphoid cells were responsible for the severe thrombocytopenia in these patients. A similar case of donor lymphocyte-induced thrombocytopenia was caused by a liver transplant obtained from a donor who died of bleeding related to severe autoimmune thrombocytopenia. Anti-gpIIb/IIIa antibodies without allospecificity were detected in both the organ donor and the posttransplant recipient serum.³⁰⁹

Platelet Transfusion Refractoriness

Nonimmune patient-dependent factors usually are involved when unexpectedly poor platelet count increments are observed after transfusion. Although ABO or HLA incompatibility and platelet storage can contribute to reduced platelet

count recovery,^{276,310,311} and ³¹² more often septicemia, drugs, and increased platelet consumption in severely thrombocytopenic patients are responsible for platelet transfusion refractoriness.

Although there is only anecdotal evidence that platelet-specific alloantibodies can cause platelet transfusion refractoriness,^{263,313} some refractory patients do benefit from transfusion with platelets that are HLA and platelet alloantigen compatible.³¹⁴ However, in a prospective study, platelet-specific alloantibodies accounted for, at most, 5% of the patients with platelet transfusion refractoriness.³¹⁵ Depletion of leukocytes prior to storage of platelets for transfusion has reduced the incidence of platelet transfusion refractoriness.³¹⁶

Platelet Polymorphisms as Risk Factors for Cardiovascular Disease

There is increasing evidence that ischemic vascular disease may result from interactions between environmental factors (e.g., smoking), genetic susceptibility, and concurrent diseases (e.g., diabetes). There is good evidence to show that platelets can play a major role in the formation of an occlusive thrombus at the site of a ruptured atherosclerotic plaque.³¹⁷ The rate of formation or the susceptibility for platelets to participate in thrombus formation may depend partly on factors that include certain polymorphisms on the platelet glycoproteins.

Measures of platelet reactivity using in vitro assays demonstrate heterogeneous results, indicating that there is a range of platelet reactivity among individuals. For example, some individuals' platelets may be considered hyperreactive based on the lower epinephrine dose threshold that induces platelet aggregation. The major platelet glycoproteins that function as receptors and mediate aggregation and adhesion can also differ antigenically and structurally between individuals. Recent evidence suggests that certain polymorphisms on glycoproteins IIb/IIIa, Ib/IX/V, and IaIIa may be associated with enhanced platelet function in vivo.

Platelet aggregation is mediated by gpIIb/IIIa, the major receptor for fibrinogen and VWF. GpIIb/IIIa is highly polymorphic, having four known alleles of the α IIb subunit and eight alleles of the β 3 subunit.³¹⁸ The Leu33Pro alleles on β 3 are the most clinically important. The Leu33 allele encodes the HPA-1a alloantigen, which is highly immunogenic to some Pro33 (HPA-1b/1b) individuals. Although these alleles are distributed within the general white population with frequencies of 0.85 (HPA-1a) and 0.15 (HPA-1b), the frequency for HPA-1b was found to be almost four times higher among younger patients with myocardial infarction or unstable angina.³¹⁹ Since that first report, other studies have not been able either to establish or to exclude HPA-1b as a risk factor for ischemic vascular disease.³²⁰

However, in vitro studies indicate that gpIIb/IIIa-mediated functions such as aggregation, adhesion, spreading, and clot retraction demonstrate heterogeneity and that the HPA-1b phenotype was associated with a lower activity threshold.^{321,322} Interactions between platelet integrins and the extracellular matrix are important for cell migration, which is directly involved in restenosis after angioplasty. Recent studies using the HPA-1a or HPA-1b forms of gpIIIa transfected into Chinese hamster ovary cells demonstrated enhanced migration activity when the HPA-1b form of the protein was a constituent of the integrin complex, as either α IIb β 3 or α v β 3.³²³ Further, a reduced affinity of the platelet function inhibitor abciximab for platelets with the HPA-1b phenotype suggested that patients with this allele may have a less favorable outcome to treatment after percutaneous coronary intervention.²⁸¹ Recent reports suggest that postoperative patients on long-term mechanical circulatory support may be at higher risk for bleeding depending on their HPA-1 polymorphism.^{324,325} Other studies involving the Ile843Ser polymorphism responsible for the HPA-3 alloantigens on α IIb have not established an association with cardiovascular disease. Although small studies have reported a link with both the HPA-3a and HPA-3b antigens with either stroke or myocardial infarction, larger studies have not reported a similar association.^{326,327,328} and ³²⁹ However, a recent report in a Chinese population demonstrated an increased incidence of the HPA-3bb genotype in younger patients (<60 years) with acute ischemic stroke.³³⁰

Three dimorphisms of gpIb α have potential relevance in thrombotic risk. The Thr145Met alleles encode the HPA-2 alloantigens, which are in linkage disequilibrium with a VNTR polymorphism in the macroglycopeptide region of gpIb α . This results in a duplication of the 13-amino acid sequence one to four times (VNTR D to VNTR-A) and would result in an increasingly longer polypeptide. However, the few studies that report an association between any of the variable polymorphisms and the risk for coronary artery disease have not been supported in others.^{331,332} and ³³³ An additional polymorphism in the Kozak region of the molecule may be important for regulating the efficiency of translation of gpIb α , thus affecting the number of receptors expressed.^{334,335} However, an association between this dimorphism and a risk for arterial thrombosis could not be demonstrated in subsequent studies.^{336,337} and ³³⁸ One study from Australia did report an association between the Kozak polymorphism and ischemic stroke, suggesting that further studies may be warranted.³³⁹

The level of expression of a major collagen receptor, gpIaIIa, can vary up to threefold depending on the inheritance of linked, allelic polymorphisms in the MMRN1 (α 2 or gpl α) gene. The 807-T/C/G polymorphism segregates independently of the alleles encoding the HPA-5a/5b and HPA-13bw alloantigens. Although some studies suggested an association of the

807T allele (high receptor density) with myocardial infarction or stroke, other studies were unable to confirm this observation.^{340,341,342} and ³⁴³ However, in a large study of 2,237 male patients, an association between younger patients with the 807T allele and myocardial infarction

P.540

was reported.³⁴⁴ Evidence of a functional effect of the HPA-5 alleles was described by Kunicki et al. The binding of platelets to decorin, but not collagen, was attenuated when the platelet donor expressed at least one of the low-frequency HPA-5b alleles. In addition, antibodies to HPA-5a were able to inhibit adhesion to decorin.³⁴⁵

WHITE BLOOD CELL ANTIGENS

Antigens expressed on granulocytes, lymphocytes, and monocytes are traditionally known as self antigens. These include the human neutrophil antigens (HNAs) and HLA class I and II. Class I HLA antigens are present on every cell and tissue in the body, except for red cells, sperm, and some placental cells. Class II HLA antigens are expressed mainly on select cells of the immune system (e.g., T and B cells, macrophages, and monocytes). White cells also express some antigens that are shared with other cells, including red cells and platelets.

White cell antigens play a pivotal role in host defense, selfrecognition, and autoimmunity. White blood cell alloantigen sensitization is implicated in fetal neutropenia, febrile nonhemolytic transfusion reactions (FNHTRs), transfusion-associated acute lung injury (TRALI), graft rejection, and graft versus host disease (GVHD). Because of their high degree of polymorphism, these antigens are used as molecular “fingerprints” in forensic medicine, paternity testing, and anthropologic studies. Many white cell antigens are recognized by monoclonal antibodies, which identify proteins that are markers of differentiation, cell adhesion molecules, and various phagocytic, complement, and chemotactic receptors. These antibodies and antigens (discussed elsewhere; see Chapter 10) have been well characterized and are assigned to cluster designation (CD) antigens based on their patterns of reactivity.

In this section the major white blood cell antigens on granulocytes and lymphocytes are discussed and disease states associated with pathologic antibodies directed at these antigens are emphasized. Monocytes share some antigens with lymphocytes (including class I and II HLAs) and neutrophils (HNA-4a), but these cells are not discussed in detail.

Granulocyte Antigens

The HNA antigen system is specific to granulocytes. Granulocytes also express antigens that are shared with other tissues and cells including HLA class I and certain blood group antigens. The antigens on granulocytes were initially defined using human alloantisera, most often through the diagnosis and investigation of infants with alloimmune neonatal neutropenia. HNA-1a and HNA-1b antigens are most often implicated in alloimmune neutropenia and the availability of monoclonal antibodies has facilitated the detailed characterization of these alloantigens. In addition to alloimmune neonatal neutropenia, alloimmunization to these granulocyte antigens has been implicated in the development of FNHTRs and TRALI. Sensitization occurs when an individual lacking these antigens is exposed through transfusion or pregnancy.

Nomenclature

In 1998, the Granulocyte Working Party of the ISBT introduced the HNA nomenclature for granulocyte antigens, which replaced the old N terminology.³⁴⁶ Unlike the HPA nomenclature system for platelet alloantigens, the neutrophil alloantigen nomenclature assigns different antigens on the same glycoprotein to the same HNA antigen system, with alleles distinguished by lowercase letters. For example, NA1, NA2, and SH antigens of the old terminology are polymorphisms of the same protein, the FcγRIIIb receptor (CD16b), encoded by FCGR3B gene, and thus are designated as HNA-1a, HNA-1b, and HNA-1c in the new terminology (HNA-1 = FcγRIIIb). Seven alloantigens have been assigned HNA designations on five glycoproteins (HNA-1 to HNA-5) (Table 20.12). The HNA nomenclature does not account for the different haplotypes possible for certain genes (e.g., FcγRIIIb). It works best for antigen systems with two alleles at a single locus, but like the HPA system for platelet alloantigens, the HNA system does not define the haplotypes that may result from crossover between alleles. Thus, although the majority of base substitutions at position 266 of FCGR3B (FcγRIIIb) encoding the HNA-1c antigen have been found on the HNA-1b form of the gene, HNA-1c can also occur with variants of HNA-1b. Modifications to the nomenclature may be required in the future to clarify these issues and to address the antigen system by its molecular characterization.

TABLE 20.12 HUMAN NEUTROPHIL ALLOANTIGENS

HNA, human neutrophil antigen.

Modified from Stronek D. Neutrophil alloantigens. *Trans Med Rev* 2002;16:67-75.

HNA-1a, -1b, and -1c

One of the most immunogenic neutrophil membrane proteins is the Fcγ receptor IIIb (FcγRIIIb), a neutrophil-specific receptor that binds the Fc portion of IgG antibodies. 30% of granulocyte autoantibodies in infants with autoimmune neutropenia are specific for epitopes on this receptor, most commonly HNA-1a and HNA-1b,³⁴⁷ and most cases of alloimmune neonatal neutropenia are due to sensitization by these antigens.³⁴⁸

Together, FcγRIIIb and the highly homologous FcRIIIa form the Fc receptor class III, which binds to polymeric IgG antibodies with low affinity. FcγRIIIb is a 233-amino acid glycoprotein secured to the membrane via a GPI anchor, thus giving it lateral mobility within the phospholipid bilayer.^{308,309,311,349} cDNA analysis has revealed that five nucleotide base substitutions at positions 141, 147, 227, 277, and 349 on chromosome 1 are associated with HNA-1a/1b polymorphism of FCGR3B.^{350,351} Four of these changes encode a different amino acid, two of which result in a different glycosylation pattern because of the changes at bases 227 and 277. Thus, HNA-1b FcγRIIIb has two additional glycosylation sites, which accounts for the larger molecular mass of this form of the gene product (65 to 80 kD) compared with the HNA-1a FcγRIIIb product (50 to 65 kD). The soluble FcγRIIIb found in plasma has the same HNA antigens as those found on neutrophils, which have been shown to be the source of the soluble glycoprotein.³⁵² The frequencies for HNA-1a and HNA-1b demonstrate marked differences among different racial groups. The HNA-1a frequency in whites ranges from 0.30 to 0.37, and

P.541

that of HNA-1b ranges from 0.63 to 0.70. However, in the Asian population, the frequency of HNA-1a is higher (0.60 to 0.66) and HNA-1b is lower (0.30 to 0.33).^{353,354,355} and ³⁵⁶

The FCGR3B gene (which encodes for FcγRIIIb protein) shares homology with the FCGR3A gene. A C733T change in FCGR3A creates an early stop codon, resulting in FcγRIIIb, a GPI-anchored protein that is 21 amino acids shorter than FcγRIIIa, a transmembrane protein. At positions 227 and 349, FcγRIIIa is the same as the HNA-1a form of FcγRIIIb, but at positions 141, 147, and 277, FcγRIIIa is homologous to HNA-1b FcγRIIIb. Neither anti-HNA-1a nor anti-HNA-1b antibodies recognize FcγRIIIa, suggesting that these alloantigens depend on tertiary conformations that are modified due to changes in the membrane anchor. Genotyping procedures with genomic DNA require multisite analysis to ensure differentiation of the HNA-1a and HNA-1b partial polymorphisms on FcγRIIIa from those on FcγRIIIb.^{354,357,358}

The HNA-1c polymorphism results from an Ala78Asp change due to a C266A substitution in FCGR3B.³⁵⁸ HNA-1c is expressed on neutrophils in 4% to 5% of whites, but is expressed much more frequently (25% to 38%) in blacks.^{358,359} and ³⁶⁰ In many individuals with the HNA-1c polymorphism, the FCGR3B gene is duplicated on the same chromosome^{361,362} and in most cases, HNA-1c results from a mutation in the HNA-1b form of FcγRIIIb.

HNA-2a

The neutrophil HNA-2a alloantigen has been implicated in alloimmune neonatal neutropenia, FNHTRs, autoimmune neutropenia, and TRALI.^{363,364} It is expressed on CD177, a 58- to 64-kD GPI-anchored glycoprotein on neutrophils in 97% of whites.³⁶⁵ The function of HNA-2a glycoprotein is unclear but it is assumed to have a receptor role.³⁶⁶ It belongs to the Ly-6 gene family,³⁶⁷ which encodes proteins characterized by repeating cysteine-rich domains including the urokinase-type plasminogen activator, the reactive inhibitor of lysis receptor (CD59), and polycythemia rubra vera-1.³⁶⁸ The HNA-2a negative phenotype seems to be the result of intron fragments in the mature mRNA, which prevents expression of HNA-

2a on the cell surface and not due to a gene deficiency or deletion.³⁶⁹ This is supported by the observation that the sensitization of HNA-2a-negative individuals does not produce alloantibodies that react with HNA-2a itself, but rather with a different unrelated antigen.³⁷⁰ Unlike other neutrophil polymorphisms, the HNA-2a antigen is expressed only on a subpopulation of neutrophils and the proportion of neutrophils expressing HNA-2a has been reported to remain remarkably stable in an individual over time. HNA-2a has a higher level of expression in women compared with men.^{357,365,371}

HNA-3a (5b)

HNA-3a has been characterized as a 70- to 95-kD glycoprotein on neutrophils, but its presence on lymphocytes, platelets, endothelial, kidney, spleen, and placental cells has been indirectly assumed as a result of adsorption studies.^{366,372} Alloantibodies to HNA-3a are well-known granulocyte agglutinins and have been implicated in neonatal alloimmune neutropenia³⁷³ and TRALI.^{374,375} Indeed, alloantibodies directed against HNA-3a antigen have been frequently implicated in severe and fatal TRALI reactions.

The molecular nature and cellular distribution of HNA-3a has been recently elucidated.^{376,377} The polymorphism is encoded by an Arg154Gln substitution on choline transporter-like protein-2 (CTL2). Approximately half of HNA-3a-specific antibodies from patients with TRALI bind a cyclic peptide of arg154 CTL2, suggesting that tertiary structures distal to the antigen site may be important in the formation of the epitope.³⁷⁸ Approximately 5% of the population is homozygous for HNA-3b and would be at risk for alloimmunization to HNA-3a. The immunogenicity of the HNA-3b antigen is much lower than HNA-3a.³⁷⁹

HNA-4a (Mart) and HNA-5a (Ond)

HNA-4a and HNA-5a are high-frequency antigens localized on leukocyte adhesion molecules on granulocytes and nongranulocytic leukocytes. HNA-4a is located on the α M chain (CR3, CD11b) and HNA-5a is expressed on the α L chain (leukocyte function antigen-1, CD11a) of the leukocyte β 2 integrin family. HNA-4a results from a single-nucleotide substitution of G302A, which encodes an Arg61His exchange, and HNA-5a results from a G2446C substitution, which encodes an Arg766Thr exchange.³⁸⁰ Although sensitization by these antigens has led to alloantibody formation, only one case of neonatal alloimmune neutropenia has been linked to anti-HNA-4a antibodies.³⁸¹

Shared Antigens

Granulocytes also express antigens that are associated with other peripheral blood cells and tissues. The class I HLA antigens (HLA-A, -B, and -C) are found on granulocytes, but not in sufficient quantities to allow their detection by cytotoxicity tests used for lymphocytes. No class II HLA antigens can be detected on mature granulocytes; however, they are present on immature cells.

Detecting Antibodies to Granulocyte Antigens

The two most commonly used tests to detect granulocyte-specific antibodies.³⁸² are the granulocyte agglutination test (GAT)³⁸³ and the granulocyte immunofluorescence test (GIFT)³⁸⁴ GAT uses a microtechnique with purified granulocyte suspensions in microtest plates. GIFT is performed in microtiter plates where cell-bound antibodies are detected with fluorescein-conjugated anti-human Ig. Coexisting antibodies to HLA and other granulocyte-specific antigens may interfere with these assays. Even with the use of well-characterized test sera and procedures to eliminate HLA reactivity (e.g., absorption or chloroquine stripping), the GAT and GIFT assays have limited sensitivity and specificity. Biochemical characterization of granulocyte antigens has facilitated the development of more specific methods for the investigation of granulocyte-specific antibodies. These include antigen capture (e.g., the monoclonal antibody-specific immobilization of granulocyte antigens assay), immunoblot, and immunoprecipitation assays, similar to the assays used to study platelets.

Clinical Significance of Granulocyte Antigens

Alloantibodies

Alloantibodies specific for the HNA-1a, -1b, and -1c antigens on Fc γ RIIIb are most commonly implicated in alloimmune neonatal neutropenia.^{348,384} Affected neonates are born to mothers who lack the antigen. IgG alloantibodies in the mother may form any time after the first trimester of pregnancy (when the hematopoietic cells are developed and cross the placenta) causing the destruction of fetal neutrophils. Symptomatic infants may present with delayed separation of the umbilical cord, skin infections, otitis media, or pneumonia within the first 2 weeks of life.³⁸⁵ Although most infections are mild, overwhelming sepsis can occur, with a mortality rate of approximately 5%. The neutropenia is generally self-limiting, reflecting the transient nature of maternal antibodies in the infant, and most infants recover within 2 weeks to 6 months as the titer of the alloantibody diminishes.

HNA-1a, -1b, and -1c antibodies and to a lesser extent HNA-2a and HNA-3a antibodies have also been implicated in FNHTRs.³⁸⁶ While most of these febrile reactions to red cell concentrates appear to be caused by granulocyte-specific antibodies in the recipient that mediate destruction of the transfused cells, most reactions to platelet transfusions are the result of cytokines that accumulate in the platelet product during storage.³⁸⁷ Pre-storage leukoreduction

P.542

reduces the risk of FNHTRs. FNHTRs may also occur with the transfusion of plasma containing HLA or neutrophil-specific antibodies.

TRALI is a rare but serious complication of blood transfusion characterized by hypoxemia, respiratory distress, and pulmonary infiltrations on chest radiograph within 6 hours of a completed transfusion.³⁸⁸ Although the pathophysiology of TRALI remains uncertain, investigators have postulated that antibody-mediated leukocyte activation in the lungs results in inflammation and complement activation causing increased vascular permeability, capillary leakage, and pulmonary tissue damage.³⁸⁹ HNA-1a, HNA-1b, HNA-2a, and HNA-3a antibodies have been implicated in TRALI reactions³⁹⁰; and antibodies against HNA-3a, which are strong granulocyte agglutinins, have been associated with severe TRALI reactions. Risk factors for TRALI include the volume of the blood product transfused,³⁹¹ the type of blood product (plasma transfusions are most commonly implicated) and the underlying condition of the patient (critically ill, surgical, etc.). Pooled plasma from multiple donors (including solvent detergent-treated plasma) may reduce the risk of TRALI since the pathogenic antibody is diluted.³⁹²

Kopko et al. performed a look-back investigation on a TRALI fatality associated with transfused plasma containing anti-HNA3a.³⁷⁵ Among 36 recipients who were available for review, 15 transfusion reactions were observed in 13 patients including eight severe reactions highly suggestive of TRALI. The association between anti-HNA-3a and severe or fatal TRALI reactions remains unconfirmed in the absence of well-designed prospective surveillance studies.

Granulocyte antibodies have also been implicated in immunemediated neutropenia following bone marrow transplantation, refractoriness to granulocyte transfusions, and drug-induced neutropenia.

Autoantibodies

Primary autoimmune neutropenia is caused by granulocyte-specific autoantibodies. The syndrome occurs most often in infancy and usually resolves spontaneously by 1 to 2 years. In a serologic investigation of 240 cases of antibody-positive autoimmune neutropenia in infancy, 31% of autoantibodies showed preferential binding to granulocytes that were homozygous HNA-1a and 3% to granulocytes that were homozygous HNA-2a.³⁴⁷ Other autoantibody specificities demonstrated were FcγRIIIb (27%), CD11b/CD18 (21%), CR1 (14%), and FcγRII (2%). Secondary autoimmune neutropenia is most often associated with another autoimmune disease such as Felty syndrome, systemic lupus erythematosus, or malignancy (e.g., lymphoma). In those cases, granulocyte-specific antibodies are not as readily detectable.

Lymphocyte Antigens

Numerous monoclonal antibodies, assigned a CD designation, recognize a number of molecules associated with various aspects of lymphocyte function and differentiation. The most clinically important lymphocyte antigens are the HLAs, and they will be the focus of this section. Lymphocytes also express a number of shared antigens, including HNA-3a, HNA-4a, and HNA-5a, and blood group antigens ABH, Lewis, Ii, P1, and P.

HLA Antigens

HLA antigens are encoded by the MHC, a cluster of genes encompassing approximately one thousandth of the human genome. The MHC is located on the short arm of chromosome 6 (band 6p 21.3) and was defined initially by investigation of antibodies in individuals sensitized through pregnancy or transfusion.³⁹³ These antigens are distributed on many types of cells and tissues and are important in the regulation of the immune response. They play a primary role in graft rejection and GVHD in transplantation and transfusion. The immune response to specific antigens is controlled by immune response genes, which are also located in the MHC (for discussion elsewhere, see Chapter 18).

The HLA complex on chromosome 6 has over 200 genes, more than 40 of which encode leukocyte antigens (Fig. 20.5). Of the three coding regions in the MHC, only the class I and II antigens are involved in the immune response. The class I genes encode HLA-A, -B, -C, -E, -F, and -G, and the class II genes encode HLA-DP, -DQ, -DR, -DN, and -DO. These class I and II gene products are structurally and functionally distinct. The class III genes encode complement components C2, C4A, C4B, Bf, 21-hydroxylase, and tumor necrosis factor- α and - β .³⁹⁴

Molecular Structure

The class I HLA molecule consists of two polypeptide chains, α and β , each encoded by different genes^{395,396,397} and ³⁹⁸ (Fig. 20.6). The HLA-A, -B, and -C genes encode the larger α -chain, a 45-kD transmembrane protein with three amino acid domains. Two of these, $\alpha 1$ and $\alpha 2$, account for most of the variation in the molecule due to polymorphisms of the HLA genes. A constant region, similar to the constant region of Ig molecules, is in the $\alpha 3$ domain close to the cell membrane. The class I α -chain is noncovalently associated with a smaller molecule, β_2 -microglobulin. No polymorphisms have been reported on this 12-kD extracellular protein encoded by a gene on chromosome 15. X-ray crystallography demonstrates further similarities to Ig molecules. The membrane-proximal $\alpha 3$ domain and the β_2 -microglobulin portions of the HLA molecule have Ig-like folds, in contrast with the $\alpha 1$ and 2 portions, which form a platform topped by α helices. A groove between these helices is the binding site for a peptide fragment from a processed antigen.

Class II HLA molecules also share similarities with Igs. Like the class I molecules, they consist of a heavy (α) and a light chain (β) (Fig. 20.6). The heavy α -chain has a molecular weight of 34 kD, and the smaller β -chain has a molecular weight of 29 kD. Both chains are transmembrane molecules, each with two structural domains. Similar to the class I molecule, HLA class II has a functional antigen-binding groove formed by the distal $\alpha 1$ and $\beta 1$ domains.³⁹⁹ The $\alpha 2$ and $\beta 2$ constant regions share homology with Ig constant regions, β_2 -microglobulin, T-cell receptors, and class I heavy chains. This homology may account for similarity in the crystallographic structure of the class I and class II antigens.⁴⁰⁰

Nomenclature

The nomenclature of the HLA antigens has been standardized by the World Health Organization (WHO) nomenclature committee, which regularly reviews newly reported specificities and genetic loci from results of International Histocompatibility Testing Workshops^{401,402} and ⁴⁰³ (Table 20.13). The nomenclature specifies the region of the gene (e.g., HLA-A) and a number. Because the antigens were originally defined by the reactivity of antisera, some early specificities have been further subclassified. These specificities are called splits and usually are written to incorporate the parent antigen in parentheses (e.g., HLA-A9 is split to HLA-23[9] and HLA-24[9]). It is also common among the HLA-A and -B alleles for specific antisera to cross-react with more than one antigen. Antisera that react with one specificity in these cross-reactive groups (CREGs) may demonstrate reactions with other antigens in the same group (e.g., HLA-A2 and -A28 or -A19 [consisting of A29 to A33]).^{404,405} and ⁴⁰⁶ Those HLA regions and genes that have been defined using molecular techniques are identified using a unique nomenclature. The nomenclature for the class I antigens includes the locus name, an asterisk (*), and a four-digit number (e.g., HLA-A*0101). The first two digits of the number refer to the serologic specificity. Because both the α and β (A and B) genes are polymorphic for the class II antigens, the chain also must be specified (e.g., HLA-DRB1*0101 or HLA-DQA1*0101). The immunogenetics/HLA (IMGT/HLA) database found at <http://www.ebi.ac.uk/imgt/hla> provides a current database for sequences of the human major histocompatibility complex (HLA) and includes the official sequences for the WHO HLA Nomenclature Committee.⁴⁰⁷

FIGURE 20.5 Organization of the major histocompatibility complex (MHC) on chromosome 6. A partial gene map of the human leukocyte antigen (HLA) complex is shown. The major loci of the genes expressed in the HLA class I and class II regions are depicted, as well as the unrelated class III genes. The following genes are shown in order, but not to scale: BF (complement factor B or CBF), C2 (complement component 2), C21B (cytochrome P450, subfamily 21 or TTC21B), C4A/C4B (complement components C4A/C4B), HSP (heat shock protein), LMP (large multifunctional protease), LTA/LTB (lymphotoxins A and B), MICA/MICB (MHC class I chains A and B), P450 (cytochrome P450), PSMB8 and 9 (proteasome β 8 and 9), TAP1/TAP2 (transporter proteins associated with antigen processing), TAPBP (TAP-binding protein, tapasin), TNF (tumor necrosis factor- α), and HSPA1A/HSPA1B/HSPA1L (heat shock proteins 1A A-type/1A B-type/1A-like).

Class I Human Leukocyte Antigen

HLA-A, HLA-B, and HLA-C antigens (class Ia) are expressed on all nucleated cells and on (anucleate) platelets. In addition, soluble HLA-A and -B antigens can be found in plasma where they circulate in association with high-density lipoproteins.^{408,409,410} and⁴¹¹ Adsorption of these vesicles into other cell membranes may explain why red cells also carry these antigens. The class I antigens are products of the highly polymorphic HLA-A, -B, and -C genes.^{396,412,413} Molecular techniques have vastly increased the number of HLA-A specificities; however, it may not be appropriate to designate these as antigens, because the resulting proteins may not initiate alloantibody formation. These alleles are more correctly referred to as genetic polymorphisms. HLA-E, -F, and -G molecules (class Ib) are similar in structure to the class Ia molecule but have a different tissue distribution.^{414,415} and⁴¹⁶

FIGURE 20.6 Schematic representation of the human leukocyte antigen (HLA) class I and class II molecules. The class I and class II molecules are each composed of two polypeptide chains that are manufactured separately in the endoplasmic reticulum. A peptide-binding groove is created by the $\alpha 1$ and $\alpha 2$ peptide-binding domains of the class I molecule. A similar peptide-binding structure is created in the class II molecule by the association of the $\alpha 1$ and $\beta 1$ peptide-binding domains. The HLA class I and II molecules also have immunoglobulinlike domains ($\alpha 3$: Class I; $\alpha 1$ and $\beta 1$: Class II) proximal to a transmembrane domain and cytoplasmic tail. MHC, major histocompatibility complex.

P.544

TABLE 20.13 SEROLOGIC ANTIGENS AND DNA POLYMORPHISMS OF THE HLA SYSTEM

Locus	Serologic Antigens	Alleles
HLA-A	A1 to A80	A*0101 to A*8001
HLA-B	B7 to B81	B*0702 to B*8301
HLA-C	Cw1 to Cw10	Cw*0102 to Cw*1803
DRA	none	DRA*0101 to DRA*0102
DRB1	none	DRB1*0101 to DRB1*1612
DQA1	DQ1 to DQ9	DQA1*0101 to DQA1*0602
DQB1	none	DQB1*0501 to DQB1*0634
DPA1	DPw1 to DPw6	DPA1*0103 to DPA1*0401
DPB1	none	DPB1*0101 to DPB1*9901

tHLA, human leukocyte antigen.

Modified from Williams TM. HLA antigens and alleles. In: Simon TL, Snyder EL, Solheim BG, et al., eds. Rossi's principles of transfusion medicine, 4th ed. Hoboken, NJ: John Wiley and Sons Ltd, 2009:890.

Class II Human Leukocyte Antigen

The class II HLAs are found on lymphocytes, monocytes, macrophages, endothelial cells, activated T cells, and Langerhans cells.^{394,399} Many of these cells play an important role in initiating the immune response. The class II genes are proximal to the centromere on the short arm of chromosome 6 and consist of one α -chain (DRA) gene and one or two β -chain (DRB) genes. Therefore, one DRA- and one DRB1-encoded polypeptide are expressed by all individuals. The other DRB genes

(HLA-DRB2 to HLA-DRB9) do not always encode a polypeptide that is coexpressed with the DRB1 product. Only the DRB3, 4, and 5 gene products are associated with a DRB1-encoded polypeptide. Although two α -chain genes and two β -chain genes are found for the DQ and DP regions, only one product ($\alpha + \beta$) is expressed.⁴¹⁷

Class III Human Leukocyte Antigen

The class III region of the MHC contains a cluster of genes responsible for complement, hormones, intracellular peptide processing, and other developmental characteristics. Thus, the class III region is not actually a part of the HLA complex, but is located within the HLA region, because its components are either related to the functions of HLA antigens or are under similar control mechanisms to the HLA genes. Complement components encoded by this region include C4A, C4B, C2, and properdin factor B (Bf). The C4A and C4B loci encode C4 variants. These polymorphic genes also are responsible for the Rodgers (C4A) and the Chido (C4B) red cell phenotypes.^{418,419} and ⁴²⁰ Other proteins, including 21-hydroxylase and tumor necrosis factor- α and - β , are also encoded in this MHC region.

Methods of Detecting Class I and II Human Leukocyte Antigens and Antibodies

Both serologic and molecular techniques have been used to identify polymorphisms of the class I genes. Serologic methods use lymphocytotoxic (functional) assays, in which sera with known anti-HLA-A, -B, and -C specificities are incubated with test cells. Cell viability is monitored after the addition of complement, which damages the cell membrane of antibody-sensitized lymphocytes, allowing the uptake of dye such as eosin.^{421,422} Because of the requirement for a relatively large and informative number of specific typing sera, commercial kits are generally used for serotyping. Molecular methods can detect polymorphisms, and sequencing can identify changes at each locus. Lymphocytotoxic techniques can also identify anti-HLA antibodies. In these assays, patient serum is screened against a panel of typed cells. Generally, 30 to 60 different target cell phenotypes are required to identify the antibody specificities. These methods are used to select potentially compatible platelets for patients who are refractory to platelet transfusions.

The class II antigens have also been detected using both serologic and cellular assays. Serologic typing for the class II antigens is performed using a method similar to that used for the class I antigens; however, instead of using unfractionated lymphocytes, the typing of class II antigens is done using only B lymphocytes. These are first isolated from peripheral blood and incubated with specific anti-DR/-DQ sera to determine the class II phenotype. It is now known that a single gene does not exist for HLA-D; however, the term continues to be applied to functional assays such as the mixed lymphocyte culture, the primed lymphocyte typing test, and T-cell clones.⁴²³ Because of the limitations of the functional assays, molecular methods have largely replaced the cellular assays for HLA class II typing. This typing is used for the identification of compatible bone marrow donors and recipients.

Inheritance of Human Leukocyte Antigens

Closely linked genes on one chromosome, such as those of the MHC, are often inherited as a unit cluster or haplotype. A child inherits one haplotype from each parent, resulting in four possible phenotypes. In some cases, an individual exhibits only two or three of the four HLA-A and -B antigens as a result of homozygosity or chromosome deletions. Heterozygosity at some gene loci is only detectable by molecular-based assays and not the less sensitive serologic assays; for example, an individual may type serologically as homozygous HLA-A2 yet by molecular studies is heterozygous HLA-A*0201/HLA-A*0202.

The chance that any two of the children are completely identical is 25%. However, crossover can occur during meiosis, thus creating a new haplotype. For the MHC, there is a crossover rate of 0.8% between the A and B loci and approximately 0.5% between the B and DR loci. Because of linkage disequilibrium, alleles at linked loci are associated more frequently than would be expected. Thus, HLA-A1 (13.8%) and HLA-B8 (9%) are in linkage disequilibrium because their actual haplotype frequency (6%) is much higher than would be expected (1.3%) if they were independently inherited. Linkage disequilibrium contributes to racial differences in haplotype frequency (e.g., HLA-A1, -B8 is rare in Asians; HLA-A34 is almost exclusive to blacks). Inheritance of the class III gene cluster as a closely linked unit, referred to as a complotype, is associated with certain disease states.^{419,424}

Clinical Significance of the Major Histocompatibility Complex and Human Leukocyte Antigen

The highly polymorphic antigens of the MHC provide useful markers in forensic medicine, in paternity testing, for anthropologic studies and for disease associations.^{425,426} and ⁴²⁷ Matching across HLAs determines the suitability of donors for solid organ and bone marrow transplantation and HLA antibodies have been implicated in transfusion reactions and in platelet refractoriness.

Association with Disease

Many diseases have been associated with specific HLA-A, -B, -C, and -DR antigens and with complement allotypes and HLA haplotypes (Table 20.14),^{428,429,430,431,432} and ⁴³³ for example Hodgkin's lymphoma and the A1, B5, B8, and B18 haplotypes. However, the A1, B8 haplotype is prevalent in long-term survivors, suggesting that it may have a protective effect.⁴³⁴ Other HLA-associated

P.545

malignancies include cutaneous T-cell lymphoma, Burkitt lymphoma, cervical squamous cell carcinoma, Kaposi sarcoma, and colorectal carcinoma. Other disease associations were with the HLA-B antigens (e.g., ankylosing spondylitis and HLA-B27)^{435,436}; however, the use of molecular techniques has now demonstrated strong associations of some class II molecules with certain diseases, including autoimmune conditions. Three loci, DQB1, DQA1, and DRB1, may be associated with susceptibility or resistance to insulin-dependent diabetes mellitus.^{437,438} The α - and β -chains from each haplotype might form pairs of molecules with modified peptide-binding properties, which, together with a dosage effect, may play a role in accelerating the disease. The importance of specific peptide-binding grooves, possibly controlled by amino acids at key positions, is also demonstrated in the HLA associations with celiac disease and rheumatoid arthritis.⁴³⁹

TABLE 20.14 ASSOCIATIONS BETWEEN CERTAIN HLA MARKERS AND DISEASE

Disease	Associated HLA Antigens and Alleles	Relative Risk
Birdshot retinochoroidopathy	A29	109.0
Ankylosing spondylitis	B27	87.4
Reactive arthropathy, including Reiter syndrome	B27	37.0
Dermatitis herpetiformis	DR3	15.9
Idiopathic membranous glomerulonephritis	DR3	12.0
Celiac disease	DR3	10.8
	DR7, DR11	6.0-10.0
	DR7, DQB1*0201	Not assessed
DR11, DQA1*0501		
Sicca syndrome	DR3	9.7
Idiopathic Addison disease	DR3	6.3
Systemic lupus erythematosus	DR3	5.8
Grave disease	DR3	3.7
Myasthenia gravis	DR3	2.5
	B8	3.4
Type 1 diabetes mellitus	DR3	3.3
(insulin-dependent)	DR4	6.4
	DR2	0.19
	DQB1*0302	9.5
	DQB1*0201	2.4
	DQB1*0602	0.15
	DRB*0101	Not assessed
Goodpasture syndrome	DR2	15.9
Multiple sclerosis	DR2	4.1

	DRB1*1501	Not assessed
	DRB5*0101	
	DQB1*0602	
Pemphigus vulgaris (Ashkenazi Jews)	DR4	14.1
Postpartum thyroiditis	DR4	5.3
Rheumatoid arthritis	DR4	4.2
Behçet syndrome	B51	3.8
Psoriasis vulgaris	Cw6	13.3
Hashimoto disease	DR11	3.2

HLA, human leukocyte antigen.

Modified from Klein J, Sato A. The HLA system. *N Engl J Med* 2000;343:782-786.

Certain immune response genes are linked to HLA haplotypes, conferring an increased susceptibility to antibody formation. For example, HLA-B8-DR3-positive individuals are more prone to forming alloantibodies to HPA-1a, the major platelet antigen most commonly implicated in NAT and posttransfusion purpura.^{440,441} Although a number of mechanisms have been proposed to explain the association between certain diseases and specific HLAs, including cross-reactive antibody responses, linkage of an HLA locus with a non-HLA disease-associated gene, regulation of T-cell development, thymic selection of T-cell receptor repertoire on HLA molecules with self-peptides, and interaction of class II HLA molecules with superantigens (cross-reactive), the exact mechanisms are unknown.

Transplantation

For solid organ transplants, HLA matching has reduced graft rejection and improved graft survival, with closer matches (6/6 for HLA-A, -B, and -DR) associated with better outcomes. The importance of HLA-A, -B, and -DR matching on graft survival has been consistently observed, especially for second kidney transplants.^{310,406,442,443} and ⁴⁴⁴ Similarly, the success of bone marrow transplantation depends on the degree of HLA matching. Related HLA-identical transplantations are associated with lower rates of delayed engraftment, rejection, or GVHD than transplants with marrow from non-HLA-identical relatives.^{445,446} and ⁴⁴⁷ Nevertheless, matching for HLA-A, -B, and -DR does not eliminate the risk of acute GVHD and graft rejection^{448,449} and ⁴⁵⁰; more precise matching for DRB1, DQB, and HLA-C using molecular techniques may further reduce the risk.^{451,452} and ⁴⁵³

Transfusion-associated Acute Lung Injury

HLA antibodies have been implicated in TRALI reactions. In early studies by Popovky and Moore, class I HLA antibodies were detected in the plasma of 59% of donors implicated in 36 cases of TRALI.⁴⁵⁴ Since then, reports of the frequency of anti-HLA class I antibodies in implicated donor plasma have varied widely but support an etiologic role of these antibodies in at least some patients. In a review of 26 patients with TRALI in which antibody-antigen concordance had been demonstrated, 12 showed class I HLA specificity, 15 showed class II specificity, and three were specific for neutrophil antigens.⁴⁵⁵ The role of class II HLA antibodies in TRALI is uncertain, as neutrophils, the effector cells in TRALI, do not express HLA class II antigens. One hypothesis is monocyte activation, which is supported by the observation of monocyte activation and proinflammatory cytokine generation following the incubation of recipient monocytes with class II HLA antibodies in plasma from donors implicated in TRALI reactions.⁴⁵⁶

Platelet Transfusion Refractoriness

Immune platelet refractoriness is another transfusion complication thought to be mediated by HLA antibodies. Alloantibodies against HLA-A and HLA-B formed after exposure to prior transfusions or pregnancies cause early destruction of transfused platelets. The use of HLA-A and HLA-B-matched platelet transfusions is often beneficial in these difficult cases. When HLA-identical donors are not available, the selection of CREG-compatible HLA antigen matches or matching of highly immunogenic epitopes using molecular techniques can be used.⁴⁰⁴

Chapter 21 Transfusion Medicine

The first documented transfusion of blood in humans occurred in 1667, but it was not until almost 300 years later that transfusion became a therapeutic practicality.¹ Landsteiner's landmark discovery in the early 1900s of blood groups and agglutinating antibodies was the key that unlocked this therapeutic pathway. The development of anticoagulants, blood preservatives, and sterile collection sets in the middle of the 20th century made blood banking possible by enabling the collection and preservation of donor blood for later use.

In the past few decades, the complexity of blood banking and blood component therapy has virtually exploded. The recognition of both infectious and noninfectious complications of transfusion led to numerous practice changes involving blood donor screening, component production and modification, compatibility testing, and blood utilization. The menu of blood component options and therapeutic services has progressively expanded, along with efforts to establish evidence-based guidelines for their optimal use. Specialized recommendations have been developed for supporting specific patient populations such as immunosuppressed patients, chronic transfusion recipients, hematopoietic cell transplant recipients, and neonates.^{2,3} In the United States, all blood establishments (blood banks and transfusion services) are regulated by the US Food and Drug Administration (FDA).⁴ FDA regulations govern all aspects of blood collection, component processing, storage, compatibility testing, and administration. The FDA requires blood establishments to comply with highly stringent quality assurance standards that ensure control of processes and restrict variability. The AABB (formerly known as the American Association of Blood Banks) issues accreditation standards and recommendations that further establish the standard of practice in the US.⁵

Today, Transfusion Medicine is itself a Board-recognized clinical specialty. In addition to overseeing the complex donor center and transfusion service operations, Transfusion Medicine physicians are increasingly important participants in the clinical care team. Transfusion Medicine specialists can guide the selection of therapeutic options to best support a patient's medical needs, and can coordinate the supply and delivery of these blood components and therapeutic services.⁶ This chapter serves as an introduction to blood components and transfusion services available in the United States.

BLOOD DONATION AND COLLECTION

Donor Selection

In the United States (US), donor eligibility criteria are established and enforced by the FDA and to a lesser degree by the American Association of Blood Banks (AABB). Donor selection is undertaken with two goals in mind: to protect the health of the donor by ensuring that a donation does not place the donor at risk, and to protect the recipient by ensuring that the donor meets all health and screening criteria so that the risk of transmitting infectious agents or causing other adverse

events is minimized.² In the US, most fresh blood products are from unpaid volunteers. These donors have decreased risk of transmitting infectious agents, especially in the “window period,” when screening tests fail to detect infection.^{7,8} Paying donors for fresh transfusion products was stopped after studies in the 1970s showed that paid donors had a much higher prevalence of hepatitis.^{8,9,10,11} and¹² Commercial plasma-derivative manufacturers still use paid donors, but comply with FDA-approved donor eligibility criteria and employ pathogen reduction processes during manufacturing that reduce infectious risks, as discussed later in this chapter.

Donor Identification and Registration

Donor registration must accurately identify the potential donor, including name, birthdate, address, and phone number, so the donor can be traced if needed. Records must link donors to all prior donations and test results and be kept for at least 10 years.

Donor Information

The donor must be given educational material describing signs and symptoms of AIDS and activities associated with increased risk of acquiring human immunodeficiency virus (HIV). The donor must be informed that testing may not detect all infections, and that individuals who have engaged in risk behavior should not donate.²

Donor Health History

Information to be elicited is defined by the FDA and the AABB. The medical history is obtained by a trained interviewer, or donors may complete an FDA-approved self-administered questionnaire on paper or a computer. Responses are then reviewed with the donor by qualified staff.² The history includes a review of current health, ensuring that the donor feels well, is free of signs of infection, and that his or her cardiovascular status can tolerate an acute blood volume loss of 10% to 15%. The donor is questioned about recent exposures to blood, potential exposure to HIV or hepatitis, sexual contact with individuals at risk for HIV, needle sharing by the donor or sexual partners, travel to or residence in areas endemic for malaria or variant Creutzfeldt-Jakob disease, medications, and immunizations.

The donor must meet certain requirements of age and vital signs. The hemoglobin must be at least 12.5 g/dl. Donor weight must be sufficient so that the donation constitutes no more than a 15% loss of blood volume. There must be no arm stigmata of parenteral drug abuse.⁵

Informed Consent

The donor must sign the health history form verifying that all questions were answered truthfully, that the donation process is understood, and that he consents to testing for infectious agents transmitted by transfusion, including HIV and hepatitis.²

Additional Donor Criteria for Specific Components

Donors may be eligible to donate some blood components but not others.

Medications That Impact Therapeutic Effectiveness of Particular Blood Components

Acetylsalicylic acid (ASA) irreversibly acetylates platelet cyclooxygenase and inhibits platelet aggregation.¹³ Platelet-mediated

P.548

hemostasis is restored, however, if ASA-inhibited platelets are mixed with untreated platelets.¹⁴ After a single dose of aspirin, ASA-exposed platelets are inhibited for the rest of their lifespan, but platelets produced after clearance of the drug restore hemostatic function. Therefore, platelets from donors who have taken ASA are acceptable as long as 48 hours have elapsed from the last dose. Platelets donated within 2 days of ASA ingestion are acceptable for use if mixed with platelets from unexposed donors.⁵

Nonsteroidal anti-inflammatory drugs (NSAIDs) may impair platelet function, but the effects of many are reversible¹³—that is, platelet function is restored once the platelets are removed from the offending drug.¹⁵ Therefore, individuals taking reversible NSAIDs can donate platelets for transfusion. Individuals who are taking irreversible NSAIDs, however, or other irreversible antiplatelet agents (e.g., ticlopidine) are not eligible to donate platelets for transfusion.⁵

Warfarin reduces levels of functional blood clotting factors (see Chapter 55). Transfusable plasma units or cryoprecipitate cannot be made from donors taking this medication.⁵

TRALI Mitigation Strategies for “High Plasma Volume” Components

Studies in the early 2000s indicated that blood products containing a large volume of plasma (e.g., plasma and apheresis platelet units) were associated with a higher per unit risk of transfusion-related acute lung injury (TRALI) compared to components containing small amounts of plasma (e.g., red cell units and cryoprecipitate). Furthermore, plasma or platelet units containing donor antibodies to white blood cell (HLA and neutrophil) antigens were implicated in a substantial proportion of TRALI cases.^{16,17} In an attempt to reduce the frequency of TRALI, the AABB recommended in 2006 that blood collection agencies take steps to reduce production of high plasma volume products from donors with an increased likelihood of having WBC antibodies.¹⁸ Women with a history of pregnancy are at highest risk of being immunized to WBC antigens. Therefore, in response to AABB recommendations, many blood collection facilities have stopped making transfusable plasma components from women with a history of pregnancy or from all women. Whole blood collections are still accepted from these women, but the plasma portion of their collections is used only for cryoprecipitate production and/or manufacturing into plasma derivatives. It has been more challenging to exclude women with a history of pregnancy from plateletpheresis donations, as the platelet supply is difficult to sustain. Some blood collection facilities exclude multiparous women as platelet donors or screen them for the presence of HLA antibodies.

Directed Donations

A directed donation (DD) is a donation in which the donor directs his/her donated blood product to a specific designated patient.² The donation must usually be ordered by the recipient's doctor. DD programs exist primarily for emotional reasons, although these programs are required to be offered in certain states. In these programs, patients anticipating the need for blood can select who their donors will be. The donor is often a family member or acquaintance of the recipient. DDs are not of medical benefit where an established blood supply exists but can be useful in rare circumstances when specific characteristics of the donor's blood are medically needed (e.g., for rare HLA or blood types obtained from family members). Directed donors must meet all regular donation criteria; however, exceptions can be made if rare types are needed. Data show DDs are no more safe than regular community donations from an infectious disease perspective. Directed donors are more likely to be first-time donors, who have a higher incidence of HIV and HCV than repeat blood donors.¹⁹ DDs theoretically may have higher risk of causing transfusion complications such as (1) hemolytic disease of the newborn in future pregnancies after a woman has received blood from her husband or his relatives,²⁰ (2) TRALI in a mother to child transfusion, or (3) transfusion-associated graft-versus-host disease (TA-GVHD) from a related family donation.²¹ Directed donations from blood relatives are irradiated to prevent TA-GVHD.

BLOOD COLLECTION PROCESS

Phlebotomy and collection of blood proceed only if the donor is deemed suitable after pre-donation screening. Blood is collected in accordance with established standards⁵ and is collected either manually or with an automated collection device.

Whole Blood (Manual) Collection

The phlebotomy site is swabbed with a disinfectant.²² Blood is collected in a primary plastic collection bag with a large bore needle allowing rapid flow and mixture with anticoagulant. The volume drawn is standardized for the collection bag used (either 450 or 500 ml). The blood draw is controlled by scales that discontinue flow when the desired weight is collected. Blood and anticoagulant are mixed gently during the collection. Specimen tubes for testing are also procured. Because most whole blood units will be separated into components, the primary bag has one to three attached satellite bags allowing separation of components in a sterile closed system. The collection tubing is heat-sealed into segments that are left attached to provide samples for crossmatching. The whole blood is transported to a laboratory where it can be separated into its components (red cells, plasma, platelets).

Blood Component Separation

Whole blood is centrifuged to sediment the red blood cells (RBCs) (Fig. 21.1). Most of the supernatant "platelet-rich plasma" is pushed off into an attached sterile satellite bag. The bag containing platelet-rich plasma may then be centrifuged at a higher rate to sediment platelets. Most of the plasma is then removed into a third satellite bag. This leaves behind a platelet pellet which is then resuspended in 40 to 70 ml of residual plasma resulting in a platelet concentrate. If platelet concentrates are not going to be produced from the donation, the initial centrifugation of the whole blood is done at high speed, and the plasma is removed directly from the red blood cells and frozen. Further processing of plasma and red cell components is discussed later in this chapter.

Terminology

The whole blood in the original collection bag (450 or 500 ml) is referred to as one whole blood unit, and each component made from that unit is defined as one "unit" of that component. Because a whole blood unit constitutes approximately

10% of a donor's blood volume, each component can be considered roughly 10% replacement therapy for an adult patient.

“Closed” versus “Open” Systems

If blood component manipulation is done without opening the system to air (closed system), all components may be stored to the limit of their viability. If the bag or tubing is entered, however, the system is considered potentially open to air/bacteria, and the product outdates in 4 hours if stored at room temperature or 24 hours if refrigerated. Devices using high-temperature welds can sterilely attach additional containers or tubing to the original unit in a way that prevents entry of bacteria. With these “sterile connection devices,” blood components may be split into aliquots, filtered, or otherwise manipulated without loss of shelf life.²

Automated Blood Collection and Separation Devices: Apheresis

The word apheresis is derived from a Greek word that means to separate or to take away. Initially, it referred to a manual process in which whole blood was withdrawn from the donor and centrifuged, the plasma retained, and the red cells

returned to the donor. In 1914, Abel experimentally removed plasma from anephric dogs, and replaced it with crystalloid.²³ It was not until the advent of plastic bags that manual apheresis could be used routinely in humans. Between 1950 and 1980, manual apheresis was the primary source of plasma for fractionation.

In the 1970s and 1980s automated cell separator devices changed the approach to apheresis. This technology has become the routine collection method for many blood components and is used in the treatment of many diseases.^{2,24}

In discontinuous centrifugal devices, anticoagulated blood is collected into a spinning disposable bowl. Centrifugal force causes red cells to move to the outside of the bowl, and platelet-rich plasma moves to the inside. White blood cells (WBCs) (buffy coat) settle in between. With optical detectors, the desired component is pumped into an attached plastic blood bag. The remaining components are returned to the donor.

Continuous flow devices continuously subject incoming blood to a centrifugal force, establishing a standing cell gradient. The fraction(s) to be removed is pumped into a bag, and the rest is reinfused continuously. The extracorporeal blood volume is lower than with the discontinuous technique, and the procedure is faster. An increasing proportion of blood components are being collected using automated cell separation. These devices can collect multiple unit-equivalents of platelets, plasma, or red blood cells from one donation. Apheresis is the main source of plasma for fractionation because multiple units of plasma may be obtained without red cells and possible resultant iron deficiency. Apheresis technology is now used to collect the majority of platelets in the US and in many regions apheresis platelets have entirely replaced platelets derived from whole blood units. Apheresis platelets have several advantages. Up to three therapeutic platelets doses (equivalent to 18 whole blood-derived platelet units) can be obtained from one apheresis donation. This minimizes possible recipient exposure to infectious agents. If a donor is large enough, it is possible to obtain two RBC unit-equivalents from one apheresis donation, returning plasma, platelets, and saline to the donor to minimize volume loss. Some apheresis devices can be programmed to collect any desired combination of red cells, plasma, or platelet products from the same donation. Apheresis technology is also used for therapeutic plasma exchange (TPE) and for collection of peripheral blood hematopoietic progenitor cells (HPCs) or donor lymphocytes, as discussed later in this chapter and in Chapter 102.²

Membrane filtration can be combined with apheresis to collect plasma. Blood is pumped over a membrane with a specific pore size that permits passage of plasma but not cells. Such devices have been used to collect plasma for fractionation or to perform TPE.

Complications of Donation

Most people easily tolerate blood donation but occasional problems arise, the most common of which are from venipuncture, consisting of bruises, soreness, and hematoma. These complications may be striking but usually resolve spontaneously. Nerve irritation and/or injury (0.02% to 0.9%) and arterial puncture (0.003% to 0.01%) are less common. Donors normally compensate for volume loss by increasing heart rate and vascular resistance, but 2% to 7% of donors experience vasovagal reactions, with syncope occurring in 0.1% to 0.3%. Fatigue (8%), nausea, and vomiting (1.1%) are also seen.^{25,26,27,28} and ²⁹ Apheresis donors can develop transient symptomatic hypocalcemia (tingling or muscle cramps) from the citrate infused when anticoagulated blood components are returned to them. These symptoms are treated by slowing the flow of the device and or giving the donor oral calcium supplements.³⁰ Intravenous calcium infusions are needed only during prolonged apheresis procedures such as those for HPC collection.²⁴

P.550

Donor Testing

Every blood donation undergoes a series of tests to determine its suitability for transfusion. In the United States, the following tests must be performed on every unit collected: ABO group and Rh type, red cell antibody screen, serologic tests for infectious markers including hepatitis B surface antigen (HBsAg), antibodies to hepatitis B core (HBc) antigen, hepatitis C, HIV-1 and -2, human T-cell lymphotropic virus (HTLV)-I and -II, and syphilis, and nucleic acid tests for HIV-1 RNA, HCV RNA, and West Nile virus RNA.⁵ In 2010 the FDA recommended one-time testing of allogeneic donors for antibodies to *T. cruzi* (the causative agent of Chagas disease).³¹ Donor testing is discussed more fully later in this chapter.

Blood components are not released for transfusion unless all donor tests for infectious markers are negative.⁵ This extensive testing results in a delay of 24 to 48 hours from the time of collection until an RBC component can be released for transfusion. Platelet products are typically not available until 36 to 48 hours after collection because of additional bacterial testing (see Bacterial Contamination).

RED BLOOD CELL PRESERVATION AND STORAGE

RBCs are collected and stored in solutions that maintain their viability.

Anticoagulant/Preservative Solutions

Blood banking was not practical until anticoagulant and preservative solutions capable of preserving red cells in viable form were developed.

Citrate anticoagulant is used for essentially all transfusable blood components today. It chelates ionized calcium in blood, blocking calcium-dependent coagulation steps. After transfusion, citrate is readily metabolized by the liver.³²

During World War I, a sodium citrate and glucose solution was developed that permitted blood storage for several days. This citrated blood was used to treat shock in British and American soldiers.³² During World War II, it was found that the addition of citric acid (acid citrate dextrose [ACD]) preserved RBCs for 21 days. Continued efforts resulted in citrate phosphate dextrose (CPD) solution,³³ a modified ACD, with added NaH_2PO_4 and a higher pH. Stored in CPD, red cell phosphate and 2,3-diphosphoglycerate (2,3-DPG) are maintained at higher levels than in ACD; however, RBC viability was still only 21 days.

In the 1950s, it was noted that red cells that had lost their adenosine triphosphate (ATP) did not survive well during storage.³⁴ Nakao³⁵ showed that ATP content and posttransfusion viability of aged red cells could be improved by the addition of adenine, which allows the RBCs to maintain the adenine nucleotide pool. Simon et al.³⁶ described the maintenance of red cell ATP levels using preservatives containing glucose and low concentrations of adenine, leading to the adenine-supplemented anticoagulants now in use.^{32,37}

CPDA-1, which is CPD fortified with adenine, became available in the United States in 1978. It had been used extensively in Europe for several years before then. Initial concerns about potential toxicity of adenine proved to be unfounded. CPDA-1 is now a common anticoagulant-preservative and allows storage of RBC concentrates for 35 days.⁵

Packed Red Cells versus Red Cells in Additive Solutions

After whole blood is collected into CPD or CPDA-1, the red cells may be centrifuged, allowing removal of most of the plasma ("packed RBCs"). Approximately 20% of the anticoagulant-containing plasma must be left to provide metabolic substrate for RBCs during storage. Another approach to red cell preservation involves more complete removal of the anticoagulated plasma from the red cells ("dry pack"), followed by resuspension of the red cells in 100 ml of an additive solution. Such additive solutions contain saline, adenine, and glucose, with or without mannitol to decrease hemolysis. The storage of RBCs in additive solutions is extended to 42 days.^{2,32} RBCs in additive solution are now the most common preparations for transfusion. RBCs collected in any of the anticoagulants and preservatives must be stored at 1° to 6°C to maintain optimum function.⁵

Changes in Red Cells during Storage

Stored liquid RBCs undergo biochemical and structural changes that have major influences on their viability and function after transfusion.^{32,38,39,40} and ⁴¹

Structural Changes

A number of red cell changes contribute to decreased cell viability after storage.^{38,40,41} RBCs are normally disc shaped. Soon after storage they become spherical with surface projections (spherocytosis). Later defects include loss of membrane lipids and protein, as well as alterations in structural proteins. Loss of membrane deformability correlates with viability.³⁹ The more severe membrane changes are irreversible and probably contribute to decreased posttransfusion RBC survival.^{38,40}

Blood bag plasticizers appear to influence membrane stability. Red cells are stored in polyvinyl chloride (PVC) bags that contain the plasticizer di-2-ethylhexylphthalate (DEHP). Morphologic deterioration is greater in RBCs stored in containers that do not have DEHP, with increased hemolysis and loss of deformability, suggesting that DEHP has a direct membrane stabilizing effect.^{42,43} Adding DEHP can both prevent and repair deterioration of stored red cells, with many of the spherical cells reverting to normal discoid morphology.⁴⁴ However, concerns have been raised about potential toxic effects of DEHP. Efforts are being made to find alternatives to DEHP.⁴⁵

Biochemical Changes

During storage, red cells metabolize glucose, producing lactic and pyruvic acid, resulting in lower pH and decreased glycolysis. As glycolysis slows, RBC ATP content falls. Because human RBCs contain no enzymes to synthesize adenine or other purines de novo, the nucleotide pool gradually becomes exhausted. In the presence of adenine, ATP may be

regenerated. Understanding this has led to prolonged RBC storage by the addition of exogenous adenine and inorganic phosphate, both of which improve the cells' ability to regenerate ATP.³²

Red cells lose potassium and gain sodium during storage. This is because the $\text{Na}^+ - \text{K}^+$ gradient is normally maintained by a $\text{Na}^+ - \text{K}^+$ ATPase that does not function well at 4°C. Gamma irradiation of red cells to prevent graft-versus-host disease (GVHD) (see section GVHD) doubles the rate of potassium leakage.^{46,47} Red cells reabsorb potassium after transfusion.⁴⁸

Red Cell 2,3-Diphosphoglycerate

Another significant change in stored RBCs is 2,3-DPG depletion, which decreases RBC oxygen delivery.^{32,49,50} In blood preserved in ACD, 2,3-DPG drops to below 50% within 48 hours. In CPD, CPDA-1, and additive solution-stored red cells, 2,3-DPG is better maintained but is still depleted after about 2 weeks. Studies show that if RBCs are cooled down rapidly to 17 to 18 degrees C within 1 hour after collection, the fall of 2,3-DPG can be delayed

P.551

significantly.⁵¹ 2,3-DPG levels improve rapidly within the first 6 hours after transfusion, and return to near-normal levels within 24 hours.^{48,52}

The clinical implications of transfusion of blood with decreased 2,3-DPG content is controversial^{32,53} The oxygen dissociation curve of cells that are 2,3-DPG-depleted is shifted to the left, resulting in increased hemoglobin oxygen affinity and decreased tissue oxygenation. These changes are thought to be of limited clinical significance because the stored red cells rapidly regain their 2,3-DPG in the circulation. In select patients, such as those in shock, lower RBC 2,3-DPG levels may have a negative effect. However, the acidosis that may be present in such patients shifts the oxygen dissociation curve to the right. Because of such compensatory mechanisms, the need for blood specifically altered to preserve or reconstitute red cell 2,3-DPG has not been demonstrated.

Rejuvenating Solutions

A number of chemical agents—dihydroxyacetone,⁵⁴ pyruvate,⁵⁵ phosphoenolpyruvate,⁵⁶ and inosine⁵⁷—are capable of maintaining near-normal red cell 2,3-DPG content during storage, or of replenishing 2,3-DPG after storage. Although none of these chemicals are likely to be used in transfusion because of their side effects, studies with these agents have resulted in the development of rejuvenating solutions.

Rejuvenating solutions contain pyruvate, inosine, glucose, phosphate, and adenine, and may be added to red cells up to 3 days after the expiration date. Treatment with rejuvenating solutions corrects the metabolic defects of the red cell, with a return to normal levels of ATP and 2,3-DPG. These rejuvenated red cells may either be washed and transfused within 24 hours or frozen for later use.² Such rejuvenated red cells have a normal survival and oxygen affinity.^{58,59} and⁶⁰ In practice, rejuvenation is rarely performed.

In Vivo Recovery of Stored Red Cells

After transfusion of stored blood, red cells that have developed lethal degrees of damage are removed promptly from the circulation of the recipient. Red cells that survive the first 24 hours after transfusion have normal survival thereafter.^{61,62} Therefore, the criterion by which the adequacy for transfusion of banked blood is assessed is the proportion of transfused red cells that remain in circulation at 24 hours after transfusion. Generally, 75% survival at 24 hours is considered evidence of adequate viability; the anticoagulant systems in current use readily achieve this goal. Work to develop optimal additive solutions capable of maintaining red cell ATP and 2,3-DPG levels and to prolong red cell storage time continues.

Clinical Implications of Stored Blood

Whether the age of transfused blood affects clinical outcomes is highly controversial, with many studies coming to different conclusions^{63,64} For a variety of complex methodologic reasons, the ability of even well-designed randomized controlled trials to demonstrate significant clinical differences based on the age of transfused blood has been questioned.⁶⁵

Frozen Red Cells

Red cell freezing is a labor-intensive process that is used primarily for storing rare blood types or prolonged storage of autologous red cells in the event of planned or postponed surgery. Glycerol is gradually added to the red cells as a cryoprotectant to a final concentration of 40% (weight/volume). The cells are then frozen at -65°C or colder for up to 10 years. Immediately after thawing, an automated cell processor must be used to wash the glycerol from the cells. The washed cells are resuspended in isotonic saline and glucose. In most cases, postthaw storage is limited to 24 hours

because an open system is used to process the cells.² However a closed system maintaining sterility has been developed and RBCs processed in this manner can be stored in a refrigerator for up to 2 weeks after thawing.^{66,67}

Potential new technologies for RBC biopreservation are now under investigation, such as hypothermic storage and lyophilization. Hypothermic red cell storage potentially maintains higher levels of 2,3-DPG but still requires improvements. Lyophilization of red cells potentially would allow stable, indefinite, room temperature storage and would be ideal for remote storage and military applications. These methods have still not been sufficiently developed.⁶⁸

PLATELET PREPARATION AND STORAGE

Preparation of Platelet Concentrates

Platelets, like erythrocytes, are actively metabolizing cells and require specific conditions for their preparation and storage to optimally maintain viability and function.^{69,70} They are prepared for transfusion either as platelet concentrates from whole blood or by apheresis. Although the preparation differs, both products are stored under the same conditions.

Platelet concentrates may be prepared from whole blood collected into bags with satellites (Fig. 21.1). The anticoagulants in current use, CPD and CPDA-1, are satisfactory for preparation of platelet concentrates. The whole blood is kept at room temperature and must be processed within 8 hours of collection. The unit of whole blood is centrifuged at low speed at room temperature, and the supernatant, platelet-rich plasma is expressed into a satellite bag. The supernatant is centrifuged again to further concentrate the platelets. Most of the supernatant platelet-poor plasma is expressed, and after 1 hour, the platelets are gently resuspended in the remaining plasma (50 to 60 ml). Approximately 60% to 75% of the donor platelets, or a minimum of 5.5×10^{10} platelets/unit, are recovered.⁷¹

In Europe and Canada, whole blood platelet concentrates are prepared from the buffy coat.² Briefly, the whole blood unit is spun inverted at high speed, and the platelet-poor plasma and the buffy coat are withdrawn, each into its own satellite bag. The buffy coat is then centrifuged at low speed to separate the platelets from the red and white cells. The functional quality of these platelets is comparable to those prepared by the American method.⁷¹ Platelet concentrates prepared from buffy coat contain fewer white cells than those prepared from platelet-rich plasma, although filtration is necessary to meet the European standards for leukoreduced products. In some European countries, platelet concentrates are pooled, resuspended in an additive solution, and filtered before storage.⁷² In the United States and Canada, the pooling of platelets before storage has been evaluated^{73,74,75}; currently, only one system has been FDA-approved for this use in the US.⁷⁶

Apheresis (Pheresis) Platelets

In the US the majority of platelets are collected from single donors by apheresis using the automated collection devices described earlier.² Platelets collected in this way must contain at least 3×10^{11} platelets in approximately 300 ml of plasma by AABB standards. This is equal to about six whole blood platelet concentrates. With improved apheresis technology many platelets collections are so abundant that they can be split into multiple products that still meet the 3×10^{11} requirement. Apheresis platelets are leukocyte-reduced by the collection technology. Because the procedure

P.552

is carried out in a closed system, the platelets can be stored for 5 days in the appropriate plastic bag.^{2,5,77} Apheresis platelets are usually collected from random donors but can also be collected from HLA-compatible donors to support alloimmunized patients. There is no significant functional difference between apheresis platelets and those from whole blood donations.⁷⁵ However, pheresis platelets typically contain fewer WBCs and, therefore, are less likely to cause febrile transfusion reactions than whole blood-derived platelet concentrates,^{78,79} unless these concentrates have been leukoreduced prior to storage.^{80,81} The use of apheresis platelets also results in fewer donor exposures for recipients.

Platelet Storage and Functional Integrity

Platelet products must be kept under specific conditions to ensure optimal recovery and function. Unlike red cells, platelets stored at 4°C undergo shape changes and lose their viability. Platelet survival and function are optimized by storage at room temperature (20° to 24°C).^{82,83} During storage, platelets metabolize glucose to lactate and hydrogen, which are buffered by bicarbonate present in the plasma, resulting in a release of CO₂. The nature of the bag in which platelet concentrates are stored is important. The plastics used in the early era of platelet transfusion were made of PVC and plasticizers and were not permeable to O₂ and CO₂. In these bags, stored platelets become depleted of oxygen, resulting in a shift from oxidative to glycolytic metabolism, with increased lactate generation, decreased pH, and decreased platelet viability. As the pH decreases below 6.2, platelets undergo shape change, are damaged, and show

reduced in vivo recovery. The platelets could not be stored for longer than 72 hours in the PVC bags. The plastic blood bags currently in use are more gas permeable. This permits continued oxidative metabolism and prolongation of storage time.^{84,85} and ⁸⁶ Although platelet viability is maintained for up to 7 days in the new plastic containers,^{87,88} storage of platelet concentrates at room temperature is currently approved for only 5 days in the US because of the risk of bacterial growth.^{89,90} Viability is best preserved if the platelets are gently agitated during storage. Platelets must be stored in sufficient plasma to maintain a pH greater than or equal to 6.2.⁵

Even under optimum storage conditions, platelets, like red cells, develop a storage lesion.⁹¹ After storage at room temperature, the changes that occur in the platelets include decreased aggregation in response to single platelet agonists such as adenosine diphosphate, and reduction in adenosine diphosphate and ATP content both in granules and in the metabolic pool. Beta-thromboglobulin and platelet factor-4 are released, and both dense and alpha-granules are depleted. There is increased surface expression of P-selectin (CD62), a molecule derived from the alpha-granule membrane of the resting platelet. Platelets may develop morphologic changes and impaired responses to hypotonic shock. It has been difficult, however, to correlate the clinical response to platelet transfusions with specific in vitro findings.

The in vivo effectiveness of stored platelets is dependent on the recovery of transfused platelets in the circulation of recipients. This has been assessed through platelet recovery and survival studies in normal volunteers using autologous radiolabeled platelets.⁹² Platelet recovery is the percentage of transfused platelets that are found in circulation immediately after transfusion. Even when fresh platelets are transfused, only about two thirds of the transfused platelets are recovered in the circulation⁹³; the remaining 30% to 40% are pooled in the spleen.⁹⁴ At the end of storage, mean platelet recovery is approximately 40% to 50%.^{86,95} After the initial recovery, there is little difference in survival of fresh versus stored platelets; both show a half-life of 3 to 5 days in healthy adults.⁸³ In patients, however, the observed recovery and survival of transfused platelets are often substantially lower than these figures (as discussed in the section Dosage and Expected Response).

The in vivo hemostatic efficacy of transfused platelets is difficult to assess. The use of bleeding times in thrombocytopenic patients as an indicator of function is not of value because of great variability in technique and lack of reproducibility of results.⁹⁶ Function is best assessed through clinical assessment of hemostasis.⁹⁷ The clinical response generally correlates with the posttransfusion platelet increment.

Platelet Additive Solutions

Platelet additive solution (PAS) use is less developed than additive solutions for RBCs, especially in the US. Removal of variable amounts of plasma and storage of platelet in PAS has many potential advantages, including optimized survival, decreased adverse reactions (e.g., allergic, febrile, TRALI), and pathogen inactivation.⁹⁸

PAS generally contain acetate, which functions both as a metabolic substrate and as a buffer. Platelets stored in one of these solutions (platelet additive solution-2) showed increased P-selectin expression and decreased in vivo recovery compared to platelets stored in plasma^{72,99}; moreover, platelets stored in the additive solution resulted in lower transfusion responses.^{99,100} Another solution, platelet additive solution-3, however, appears to show suitable preservation of platelet function for 7 days and is now in use in both Europe and the US. Platelet additive solutions are included in the pathogen reduction systems for platelets that are approved in Europe. These systems include exposure of the platelets to pathogen reduction agents and UV light, as discussed later in this chapter. This processing appears to be associated with some loss of platelet product potency, but the clinical importance of these changes is unclear.^{101,102}

Frozen Platelets

Frozen storage of platelets has been investigated and a potential role of such preparations has been established only for patients with alloantibodies for whom satisfactory donors cannot be found. Autologous platelets may be frozen using dimethyl sulfoxide as the cryoprotective agent. In vitro recovery of frozen and thawed platelets and posttransfusion increments may be satisfactory for clinical use, although only approximately half of the platelets survive the freeze-thaw process.^{103,104} This recovery may be improved by combining a platelet additive solution with a reduced concentration of dimethyl sulfoxide.¹⁰⁵ Theoretically, autologous frozen platelet transfusions may permit support of highly alloimmunized patients through periods of chemotherapy-induced myelosuppression.^{104,106} Currently, frozen platelets are not available for clinical use; however, studies are beginning to evaluate preserving platelets by freeze-drying with trehalose.^{107,108}

PREPARATION OF PLASMA COMPONENTS

Plasma is obtained from whole blood donations and apheresis collections. The plasma may be used for transfusion, further processed by the blood center into cryoprecipitate, or sent to commercial facilities for manufacturing into plasma derivatives.

Plasma Components for Transfusion

Plasma components such as FFP and cryoprecipitate are produced from individual volunteer blood donations and are briefly described here. As noted earlier, transfusable plasma units are not typically made from donors with an increased likelihood of having antibodies to WBC (e.g., women or women with a history of pregnancy); this strategy reduces the TRALI risk associated with plasma transfusion.

P.553

Fresh Frozen Plasma, Plasma Frozen within 24 Hours (FP24)

Fresh frozen plasma (FFP) is prepared by separating citrated plasma from whole blood and freezing it within 8 hours of collection or by freezing citrated apheresis plasma within 6 hours of collection. Each unit of FFP prepared from whole blood contains approximately 200 ml of plasma. Apheresis plasma may be packaged into 200- or 400-ml bags. FFP may be stored at -18°C or below for up to 1 year. Under these conditions, there is minimal loss of activity of the labile coagulation factors V and VIII. One milliliter of FFP contains approximately one unit of coagulation factor activity. After thawing, FFP may be stored in the refrigerator for up to 24 hours before use.

A product called "Plasma frozen within 24 hours after phlebotomy" (FP24) has largely replaced FFP production in the United States. As discussed earlier, TRALI mitigation strategies have restricted the donations from which transfusable plasma units can be made. In order to maintain a sufficient supply of plasma components for transfusion, most blood collection facilities in the US are labeling their plasma units as "Plasma frozen within 24 hours after phlebotomy" rather than "FFP." This labeling permits blood centers to make transfusable plasma units from donations that reach the component processing facility more than 8 hours after collection. The content of FP24 is identical to that of FFP except that the Factor VIII content may be reduced to 80% that of FFP.^{109,110,111} This Factor VIII content is more than sufficient for the therapeutic applications in which plasma is utilized, e.g., trauma, liver disease, warfarin reversal, etc. Therefore, FFP and FP24 are typically used interchangeably.¹¹²

Liquid Plasma, Thawed Plasma

Liquid plasma is a term for plasma that is separated from whole blood and stored at 1°C to 6°C without freezing. Thawed plasma is a term for FFP or FP24 that is thawed and stored in the refrigerator for up to 5 days after thawing. The only significant difference between these products and FFP/FP24 is the content of the labile coagulation factors (V and VIII).

After 5 days of refrigerated storage, Factor VIII and V levels are at about 65% to 75% of their original levels. After 28 days' storage, Factor VIII activity is approximately 40% of normal and Factor V levels approximately 50% to 60% of normal. Other coagulation factors, including fibrinogen, ADAMTS 13, and factors II, VII, IX, X, and XIII, are generally stable under refrigerated storage conditions.^{112,113,114,115} and ^{116,117}

Liquid plasma or thawed plasma should not be used for clotting factor replacement in patients who have specific deficiencies of factor V or VIII. However, these products can be used for plasma replacement in massively bleeding patients, as these products will still maintain clinically hemostatic factor levels in the patient (i.e., 30% of normal). Because Vitamin K-related factors are not depleted during refrigerated storage, these prolonged storage products would be equivalent to FFP or FP24 for warfarin reversal.

Plasma, Cryoprecipitate Reduced

This is the supernatant remaining after removal of cryoprecipitate from FFP (see "Cryoprecipitated Antihemophilic Factor"). Storage conditions are the same as for FFP. This product is deficient in fibrinogen, Factor VIII, von Willebrand factor (vWF), and factor XIII. Cryoprecipitate-reduced plasma was initially thought to be superior to FFP for treatment of TTP because of its lower vWF content. Randomized studies have verified that this fluid is therapeutically effective for TTP; however, it is not superior to FFP.¹¹⁸

Cryoprecipitated Antihemophilic Factor

Cryoprecipitated AHF, or cryoprecipitate, is an extract of FFP that is enriched in high-molecular-weight plasma proteins. It is prepared by thawing one unit of FFP at 1°C to 6°C . Under these conditions, the high-molecular-weight proteins remain

as a precipitate. The precipitated protein is concentrated by centrifugation, and all except approximately 15 ml of supernatant is removed. The remaining 15 ml and the precipitate are refrozen. Each unit of this cryoprecipitate contains approximately 80 to 120 units of Factor VIII and at least 150 mg of fibrinogen. It also contains factor XIII, fibronectin, and the high-molecular-weight multimers of vWF.

Cryoprecipitate was originally developed for the treatment of hemophilia A. It is no longer the treatment of choice for that disorder, because less infectious alternatives are available. At the present time, cryoprecipitate is most often used for correction of hypofibrinogenemia (<100 mg/dl) in bleeding patients. Cryoprecipitate has also been used topically, along with thrombin and calcium, as a "fibrin glue." However, commercial products that are much more effective as topical hemostatic or sealant agents are now available. A commercial fibrinogen concentrate for intravenous infusion is available, but as of April 2012 this product was approved in the US only for treatment of congenital fibrinogen deficiency.

The typical dose of cryoprecipitate of one unit per 5 to 10 kg can be expected to raise the recipient's fibrinogen level by approximately 70 mg/dl.^{2,3} Multiple units of cryoprecipitate are often pooled before administration.

Commercial Plasma Derivatives

Commercial plasma derivatives are made from pooled plasma collected from hundreds or thousands of donors. In the United States, paid plasmapheresis donors provide most of the plasma derivatives, but excess ("recovered") plasma from volunteer whole blood donations is used also. Plasma units are pooled and fractionated into a number of purified proteins. The most commonly used fractionation procedure is based on Cohn's cold ethanol fractionation process, developed in the 1940s.¹¹⁹ As the temperature, ionic strength, pH, and ethanol concentration are varied, plasma can be separated into several fractions. Fraction I contains Factor VIII and fibrinogen, fraction II contains the immunoglobulins, and fraction V contains albumin. Fractions III and IV contain a number of other coagulation factors and proteins. Although other approaches such as ion-exchange chromatography have been applied to the preparation of certain plasma products, Cohn's method remains the standard.

Because the plasma pools used for the production of plasma derivatives are derived from many donors, contamination with infectious agents is common. All plasma derivatives are treated by methods demonstrated to inactivate HIV, HCV, and hepatitis B virus (HBV), such as prolonged heat and treatment with organic solvents and detergents, which inactivates lipid-coated viruses. Pooled plasma products, however, could still transmit infectious agents that lack a lipid coat and that are resistant to heat. Human parvovirus B19 is one such agent. The FDA requires screening for, and exclusion of, donations that contain high titers of the B19 virus,¹²⁰ but low levels of B19 virus can still be present in the pools. Many plasma derivatives undergo additional purification steps such as affinity chromatography, precipitation, or nanofiltration that would further reduce their contamination by infectious agents.^{119,121}

There are many commercial plasma derivatives available. Some examples are described in the following.

Solvent/Detergent-treated Plasma

Solvent/detergent-treated plasma is made from hundreds or thousands of units of FFP that have been thawed, pooled, subjected to treatment with organic solvents and detergents, filtered, and refrozen.¹²² The product was developed to reduce the risk

P.554

of transmitting enveloped viruses, such as HIV, HCV, and HBV. It appears to be therapeutically equivalent to FFP.¹²² A version of this product introduced in the US in the late 1990s was withdrawn after reports of thromboembolic complications. European versions of this product, however, are in current use and have a good safety record. In contrast to individual plasma units, this pooled plasma product has not been associated with transfusion-related acute lung injury (TRALI), presumably because of dilution of antibodies from individual donors during plasma pooling.

Coagulation Factor Concentrates

The coagulation factor concentrates, both the recombinant products and those made from plasma, are discussed in detail elsewhere as part of the management of inherited or acquired coagulation disorders (see Chapters 53 and 54). Recombinant coagulation products are used when available; these include Factors VIII, IX, and VIIa. Some factors are available only as plasma-derived concentrates, including fibrinogen and protein C.

Immunoglobulins

Intramuscular immune globulin preparations are prepared from pooled plasma by cold ethanol fractionation. They contain dimeric and polymeric IgG, artifacts of the fractionation procedure, which are capable of nonspecifically activating

complement by both the classic and alternative pathways. This mechanism probably explains the major adverse effects that occur if these products are administered intravenously.¹¹⁹ Products labeled for intramuscular use must therefore not be given intravenously.

Intravenous immune globulin preparations (IVIgs) are produced by various chemical modifications designed to decrease the aggregation of IgG. Nonspecific complement activation is reduced, whereas the ability of the Ig molecules to interact with pathogenic organisms and complement is retained. Many of these products may also be administered subcutaneously.

Nonspecific immune globulin preparations contain a broad spectrum of antibodies naturally present in the donor population. They are most often used for treatment of primary immunodeficiency or as immune modulators.¹²³ Immune globulins against a particular target are derived from the plasma of donors selected for high concentrations of antibodies to that target. Such preparations include Rh immune globulin, hepatitis B immune globulin, and Varicella zoster immune globulin.

IVIgs have been associated with some adverse reactions, including renal failure, hemolysis, and thrombotic events. Both IM and IV immune globulin products should be used with caution in patients with IgA deficiency, because they may contain small quantities of IgA.

BLOOD COMPONENT MODIFICATION

Leukocyte Reduction

When whole blood is separated by centrifugation, WBCs sediment at the interface between red cells and platelet-rich plasma. Therefore, WBCs typically contaminate both red cell and platelet components, with concentrations of WBCs approximately 10^9 /product. WBCs in blood components can mediate febrile transfusion reactions, stimulate HLA alloimmunization in transfusion recipients, and transmit some cell-associated pathogens such as cytomegalovirus (CMV).¹²⁴ Therefore, it is desirable to remove WBCs from transfusable blood components.

Historically, several methods have been used to reduce the number of WBCs in transfusable blood components. Relatively nonspecific methods were used initially, including saline washing of red cells or physical separation of the WBC layer (buffy coat) from the RBCs.¹²⁴ Later, microaggregate filters were used to remove WBCs after centrifugation.¹²⁵ These methods resulted in white cell reduction of 70% to 90% and were effective in preventing most febrile reactions to red cells. Freezing and deglycerolization of red cells have also been used to remove WBCs and result in approximately 2-log WBC removal. Ultimately selective leukoreduction filters were developed that can reduce WBCs from blood components by 3 or more logs. These synthetic fiber filters remove WBCs by a combination of mesh density, chemical attraction, and active adhesion.¹²⁴ All leukocyte-reduced red cells are now produced using these special filters and, by FDA criteria, have less than 5×10^6 WBCs/unit and at least 85% of the original RBC component.

Leukofiltration of RBC components may be performed at the blood collection center, in the hospital transfusion service, or at the bedside. Filtration prior to storage reduces WBC breakdown products in the blood component and there is some evidence that RBC viability is better preserved. The clinical importance of these benefits has not been demonstrated.¹²⁴ In practice, most RBC leukofiltration is performed by blood collection centers within the first few days after collection.

Apheresis platelets usually contain very few WBCs and usually qualify as leukoreduced ($<5 \times 10^6$ WBCs) without the need for filtration. In contrast, whole blood-derived platelet concentrates contain large numbers of WBCs, and many of the febrile transfusion reactions to these products appear to be due to cytokines produced by the WBCs in these products during storage.^{126,127,128} and ¹²⁹ Therefore, removal of WBCs from whole blood-derived platelet concentrates before storage is beneficial. One system is approved in the US that allows prestorage leukocyte reduction and pooling of whole blood platelets.

The use of leukoreduced products has evolved over the last decade or two. Initially these products were indicated for patients with a history of febrile, nonhemolytic transfusion reactions, to reduce the risk of HLA alloimmunization, and as an alternative to cytomegalovirus (CMV) antibody screening of donors to reduce the risk of transfusion-transmitted CMV. Now the use of leukoreduced products has become nearly universal, although the medical necessity of universal leukoreduction remains somewhat controversial.¹³⁰

Washed Products

Saline washing with automated cell washers can be used to reduce the amount of plasma in cellular blood products. These washers are capable of removing approximately 99% of plasma proteins from red cell products.² Although cell washing was previously also used for leukocyte reduction, it is no longer used for this purpose. Today, washing is primarily used to

reduce incompatible plasma and also prevent severe allergic reactions (which are thought to be triggered by donor plasma proteins). Washing is also used to reduce RBC supernatant potassium, which may be required prior to massive or rapid infusion of stored RBC to neonates. Washing on an automated cell processor takes 30 to 45 minutes/unit. Because the washing procedure is usually performed in an "open" system, the red cells have only a 24-hour shelf life after washing. A closed processing system has been developed that may permit longer storage of washed cells.⁶⁶ Although many facilities perform red cell washing, few offer washed platelets. Use of automated cell washers to wash platelets has been described.² However, in practice, it may be difficult to ensure adequate platelet recovery and viability after washing.

Irradiation of Blood Products

Gamma irradiation of cellular blood components is used to prevent transfusion-related GVHD by impairing the proliferative capacity of lymphocytes in the blood component. The recommended dose

P.555

for the irradiation of blood and blood products is 2500 cGy at the center of the irradiation field, with a minimum dose of 1500 cGy at any point in the field.^{5,131} This dose of radiation has no significant adverse effect on red cell, platelet, or granulocyte function. However, there are changes in the red cell membrane that result in an increased loss of potassium from the cell, limiting the storage time of red cell concentrates to 28 days.^{46,47} The amount of accumulated free potassium in the supernatant of irradiated red cells may be clinically important in massive transfusion, especially in the neonate.¹³² It may be desirable to irradiate proximate to transfusion, or wash stored irradiated RBCs if massive transfusion of irradiated products is required for a patient at risk for hyperkalemia. The dose of irradiation used for cellular blood components is not sufficient to inactivate pathogens.¹³³ The irradiation doses required for pathogen inactivation would irreparably damage blood components.

ALTERNATIVES TO ALLOGENEIC DONOR BLOOD

Autologous Blood

Autologous blood donation is blood donated by a patient, intended for transfusion back into the same patient. Blood collected for autologous use is not released to other patients.

Use of a patient's own (autologous) blood may reduce or eliminate the need for allogeneic blood. There are three types of autologous blood collection procedures. In preoperative autologous donation (PAD), patients donate one or more units of blood to a blood bank during the weeks preceding an elective procedure. In acute normovolemic hemodilution (ANH), blood units are collected in the operating room immediately prior to surgery. In autologous blood cell salvage, blood lost during or after a surgical procedure is salvaged for reinfusion.

Preoperative Autologous Donation

Preoperative blood donation (PAD) is most often used for patients who are expected to require transfusion during elective surgery. It is also used in patients for whom crossmatch-compatible blood cannot otherwise be made available, as in patients with rare blood groups or with multiple alloantibodies. For autologous collections, the donor eligibility criteria are not as stringent as for allogeneic donors. The key consideration is whether the patient can tolerate the acute withdrawal of a unit of whole blood representing 10% to 15% of their blood volume. Patients with significant cerebral or cardiac disease should be evaluated before they are enrolled in a PAD program. Children are also eligible for autologous blood donation, but the volume of blood collected and anticoagulant used must be adjusted to body weight.

An autologous donor may donate blood every 3 days as long as the donor's hemoglobin remains at or above 11 g/dl. An "aggressive" donation schedule stimulates a more substantial endogenous erythropoietin response, with the potential for more autologous units collected or a higher patient hemoglobin at surgery.¹³⁴ In most instances, the units of blood are stored in the liquid state for up to 35 to 42 days. They may be frozen if a longer interval between donation and surgery is required, but this significantly increases the cost and is not routinely recommended.^{135,136}

All autologous collections must be tested for ABO group and Rh type. The units must be labeled For Autologous Use Only. If autologous blood is to be transfused at an institution that is not the collecting facility, the blood unit must be tested for transfusion-transmitted infectious diseases.⁵ Units with reactive infectious disease tests must be labeled with biohazard labels. Regulators permit the use of autologous units with positive infectious disease tests. However, some hospitals do not accept such units because of concerns related to the risk of accidental transfusion of the unit into the wrong patient.

PAD is not necessarily beneficial to the patient. There is a reported 12-fold increase in the number of autologous donors hospitalized after a donation compared to allogeneic donors, with an increased risk in the elderly.¹³⁷ Iron supplementation

is recommended, but may not be sufficient to prevent anemia, especially if the last unit of autologous blood is collected <7 days preoperatively. This anemia may increase the patient's likelihood of requiring transfusion.¹³⁸ PAD is expensive and the logistics of collecting and shipping the blood in the desired timeframe are complex. Autologous blood may be wasted or transfused unnecessarily, particularly if collected for procedures in which transfusion is rarely needed.^{139,140}

Transfusion complications such as bacterial contamination, febrile nonhemolytic transfusion reactions (FNHTRs), allergic reactions, and volume overload can occur with autologous transfusion.¹⁴¹ The possibility of an accident or error such as the transfusion of the wrong unit or an allogeneic unit into the autologous donor/patient has been reported to be as high as 1.2%.¹⁴² The cost-effectiveness of PAD is has been questioned, given its high cost, risks, and limited benefit.¹⁴³

Acute Normovolemic Hemodilution

The second approach to autologous blood procurement involves the withdrawal of blood immediately before the surgical procedure and replacing the blood with crystalloid, colloid, or both, thereby acutely lowering the patient's hematocrit.^{139,144} The blood lost during surgery is therefore relatively dilute, reducing total red cell loss. The higher hematocrit blood withdrawn immediately prior to surgery is used for transfusion. Patients most likely to benefit from this maneuver are those with anticipated large surgical blood losses who can tolerate low intraoperative hematocrits.^{145,146}

Units collected by ANH can be stored at room temperature for up to 8 hours or at 1°C to 6°C for up to 24 hours.¹⁴⁷ The blood so collected does not undergo any storage-related changes. The relative efficacy of ANH in comparison to other blood conservation techniques has been debated.^{146,148,149} The cost of ANH is significantly less than that of PAD because there is little incremental cost associated with collecting the blood and no required testing.¹⁴⁹

Intraoperative and Postoperative Salvage and Reinfusion

A third approach to autologous transfusion is the collection and retransfusion of blood lost during or after surgery.^{2,150} Perioperative salvage has been shown to be effective in reducing the need for allogeneic blood in a variety of surgical procedures. The AABB publishes Standards for Perioperative Autologous Blood Collection and Administration, which provide guidance for use of these blood conservation options.¹⁴⁷

There are two basic techniques available. Intraoperatively, an anticoagulated vacuum suction device can be used to collect blood from the surgical field and deliver it to a centrifuge-like device that washes the shed blood with saline before it is reinfused. Only red cells are salvaged by this method (platelets and plasma are lost). There has been concern about the safety of reinfusing materials suctioned from obstetric, cancerous, or contaminated surgical fields. Published experience to date, however, suggests that reinfusion of salvaged cells after processing with leukoreduction filters may be safe in these settings.¹⁵¹ Postoperatively, blood shed into joints or body cavities can be collected into sterile containers. The salvaged material must be filtered to remove fat and particles, and may then be reinfused either directly or after washing. The shed fluid contains red cell stroma, free hemoglobin, activated clotting factors, and fibrin degradation products.

P.556

It appears that there is not an increased risk associated with infusion of unwashed shed blood if the volume reinfused is limited to approximately 1 L. There is little value to salvaging shed blood in settings where the volume of fluid drained from the surgical site is small or has a low hematocrit. Because these devices are expensive, patient selection is important.¹⁵²

Erythropoiesis Stimulating Agents

Erythropoiesis stimulating agents (ESA) have been used to stimulate red cell production in patients, either to increase the number of units that can be collected preoperatively^{134,153,154} or to increase preoperative red cell mass.¹⁵⁵ The use of epoietin alfa has been approved to facilitate autologous blood donation in the European Union, Canada, and Japan, but not in the United States.¹⁵⁶ Epoietin alfa has also been approved for perisurgical use in anemic patients (Hgb ≤13 g/dl) in the US and Canada.

Artificial Oxygen Carriers

Some aspects that make the artificial oxygen carriers particularly appealing include: the prospect of being free of most or all of the infectious risks of allogeneic blood; no need to perform blood grouping and cross match; extended shelf life and possibility of storage at room temperature; the potential for a virtually unlimited supply; and the possibility of development of homogeneous and standardized products with controlled characteristics optimized to achieve the goal of oxygen delivery without raising all other complexities of allogeneic blood.^{157,158,159} and ¹⁶⁰ No artificial oxygen carrier is currently approved by the FDA for clinical human use in the US.

Perfluorocarbon (PFC) emulsions boost oxygen delivery by increasing the amount of dissolved oxygen. Use of these oxygen carriers must be coupled with oxygen and increased FiO_2 to further increase the amount of dissolved oxygen. The PFCs that reached clinical trials include Fluosol-DA (Alpha Therapeutics, Los Angeles, CA) and Oxygent (Alliance Pharmaceutical Corporation, San Diego, CA). Fluosol-DA was initially used to improve oxygen delivery to the heart muscle during percutaneous transluminal coronary angiography, but it was subsequently withdrawn because of difficulties in storage and preparation, and lack of utilization in angioplasty.

Hemoglobin-based oxygen carriers (HBOCs) increase the oxygen delivery by increasing total hemoglobin. Despite being an effective oxygen carrier, vasoconstriction (initially attributed to extravasation of the HBOC to interstitial space and scavenging nitric oxide)¹⁶¹, hypertension, and renal, pancreatic, and liver injury have been described as complications. Approaches such as purification, polymerization, cross-linking, conjugating with other macromolecules, and encapsulating in vesicles or other nanoparticles have been pursued to minimize toxicity and associated complications in subsequent generations of HBOCs.¹⁶²

A 2008 meta-analysis of 16 trials on 5 different HBOCs indicated that regardless of the individual product or indication studied, HBOCs are associated with significantly higher risk of death (relative risk of 1.30) and myocardial infarction (relative risk of 2.71) compared to the controls.^{163,164,165} A new generation of products is in development as “oxygen bridges” until anemia management via compensatory erythropoiesis with production of cellular hemoglobin can be achieved with the use of ESA and intravenous iron therapy.

USE OF BLOOD COMPONENTS

Table 21.1 lists the blood components available for clinical use and briefly summarizes the indications for the use of each. The use of each component is discussed in detail in the following sections.

Patient Informed Consent

Although approximately 14 million units of RBCs are transfused in the United States each year, their efficacy has never been demonstrated in well-designed trials. For purposes of obtaining the patient's informed consent, the treating physicians and patient must understand that not all is known about the relative risks and benefits of blood transfusion.

The elements of transfusion consent comprise: a discussion of blood transfusion risks^{166,167} and benefits; alternatives to blood; an opportunity to ask questions; and patient consent.¹⁶⁸ Consent should occur as far in advance of transfusion as possible, so that alternatives to allogeneic blood such as autologous blood can be made available. Some states have legislated that alternatives to allogeneic blood be offered to patients whenever there is a reasonable possibility that a blood transfusion may be necessary. It should also be noted that blood transfusion has been legislated to be a medical service not subject to commerce and trade laws, thus excluding the principle of implied warranty and granting blood banks immunity from strict product liability.¹⁶⁹

Patient Blood Management

Of the estimated 39 million discharges in the US in 2004, 5.8% (2.3 million) were associated with blood transfusion.¹⁷⁰ The rate of blood transfusion more than doubled from 1997 to 2009. Increased provider awareness of the costs associated with blood transfusion¹⁷¹ and recognition of the potential negative outcomes have stimulated initiatives in Patient Blood Management.¹⁷² Blood Management has been defined as the appropriate use of blood and blood components, with a goal of minimizing their use. This goal has been motivated historically by: 1) known blood risks; 2) unknown blood risks; 3) preservation of the national blood inventory; and 4) constraints from escalating costs.¹⁷²

Patient-focused blood management¹⁷³ is an evidence-based approach that is multidisciplinary (transfusion medicine specialists, surgeons, anesthesiologists, and critical care specialists) and multiprofessional (physicians, nurses, pump technologists, and pharmacists). Preventative strategies are emphasized to identify, evaluate, and manage anemia^{174,175} (e.g., pharmacologic therapy¹³⁹ and reduced iatrogenic blood losses from diagnostic testing)¹⁷⁶; to optimize hemostasis (e.g., pharmacologic therapy¹⁷⁷ and point of care testing)¹⁷⁸; and to establish decision thresholds (e.g., guidelines) for the appropriate administration of blood therapy (the impact of these activities on blood transfusion outcomes is illustrated in Figure 21.2.^{172,179,180}

In the US, The Joint Commission (TJC) developed Patient Blood Management Performance Measures which have been placed in their Topic Library. These are available to be used as additional patient safety activities and/or quality improvement projects by provider institutions.¹⁸¹

Patient Blood Management strategies for patients undergoing cardiac surgery have been shown to be safe and effective in reducing transfusion, while at the same time delivering high-quality outcomes. One institution reported that only 11% of

patients undergoing cardiac surgeries received blood transfusions; this program ranked first in their state for lowest risk-adjusted mortality.¹⁸²

RED CELL TRANSFUSION

The main indication for RBC transfusion is inadequate oxygen delivery as a result of anemia and, in some cases, hypovolemia. Wound healing is not impaired in the presence of anemia, and transfusion does not improve wound healing. Patients with chronic diseases should never be transfused simply because of mild asymptomatic anemia or as part of supportive care.

P.557

TABLE 21.1 BLOOD COMPONENTS AND INDICATIONS FOR USE

Component	Composition	Volume	Indications and Expected Benefit
Whole blood	RBC and plasma (approx. Hct, 40%); WBCs; platelets ^a	500 ml	To increase red cell mass and plasma volume (plasma deficient in labile clotting factors V and VIII); for hypovolemic anemia, massive transfusion, or exchange transfusion in neonates
Packed RBCs	RBC and reduced plasma (approx. Hct, 75%); WBCs; platelets ^a	250 ml	To increase red cell mass in symptomatic anemia; 10 ml/kg raises Hct by 10%
RBCs, adenine-saline added	RBC and 100 ml of additive solution (approx. Hct, 60%); WBCs; platelets ^a ; little plasma	330 ml	To increase red cell mass in symptomatic anemia; 10 ml/kg raises Hct by 8%
RBCs, leukocytes reduced (prepared by filtration)	>85% original volume of RBCs; <5 × 10 ⁶ WBCs	>85% of original volume	To increase red cell mass; <5 × 10 ⁶ WBCs to decrease the likelihood of febrile reactions, immunization to leukocytes (HLA antigens), or CMV transmission
RBCs, washed	RBCs (approx. Hct, 75%); reduced WBCs; no plasma	225 ml	To increase red cell mass; reduce risk of allergic reactions to plasma proteins; or reduce free potassium dose
RBCs, frozen	RBCs (approx. Hct, 75%);	225 ml	To increase red cell mass; minimize febrile or allergic transfusion reactions; use for prolonged RBC blood storage
RBCs, deglycerolized	<5 × 10 ⁶ WBCs; no platelets; no plasma		
Granulocytes, pheresis	Granulocytes (>1.0 × 10 ¹⁰ polymorphonuclear cells/unit); lymphocytes; platelets (>2.0 × 10 ¹¹ /unit); some RBCs	220 ml	To provide granulocytes for selected patients with sepsis and severe neutropenia (<0.5 × 10 ⁹ /L)
Platelet concentrates	Platelets (>5.5 × 10 ¹⁰ /unit); RBCs; WBCs; plasma	50 ml	Bleeding due to thrombocytopenia or thrombocytopathy; 1 unit/10 kg raises platelet count by 17-50 × 10 ⁹ /L

Platelets, pheresis	Platelets ($>3 \times 10^{11}$ /unit); RBCs; WBCs; plasma	300 ml	Same as platelets; sometimes HLA-matched; benefit is equivalent to 6 platelet concentrates
Platelets, leukocytes reduced	Platelets (as above); $<5 \times 10^6$ WBCs/final dose of pooled or pheresis platelets	300 ml	Same as platelets; $<5 \times 10^6$ WBCs to decrease the likelihood of febrile reactions, alloimmunization to leukocytes (HLA antigens), or CMV transmission
FFP; thawed plasma	FFP: all coagulation factors; thawed plasma: reduced factors V and VIII	200 ml	Treatment of some coagulation disorders; 10 ml/kg of FFP raises factor levels by approximately 10%
Cryoprecipitated antihemophilic factor	Fibrinogen; factors VIII and XIII; von Willebrand factor	15 ml	Deficiency of fibrinogen, 1 unit/5 kg raises fibrinogen 70 mg/dl; also used for factor XIII replacement; not first-choice therapy for hemophilia A, von Willebrand disease, topical fibrin sealant

approx., approximate; CMV, cytomegalovirus; FFP, fresh frozen plasma; Hct, hematocrit; RBC, red blood cell; WBC, white blood cell.

^aWBCs and platelets are nonfunctional.

Modified from Triulzi DJ, ed. Blood transfusion therapy: a physician's handbook, 7th ed. Bethesda, MD: American Association of Blood Banks, 2002.

Indications for Red Blood Cell Therapy

The therapeutic goal of a blood transfusion is to improve oxygen delivery according to the physiologic need of the recipient. The usual response to an acute reduction in hemoglobin in the normovolemic state is to increase cardiac output to maintain adequate oxygen delivery.¹⁸³ The heart is the principal organ at risk in acute anemia. In a normal heart, increased lactate production and an oxygen extraction ratio of 50% occur at a hemoglobin of approximately 3.5 to 4 g/dl.¹⁸⁴ In a model of coronary stenosis, the anaerobic state occurs at a hemoglobin of approximately 6 to 7 g/dl.¹⁸⁵ No single number, either extraction ratio or hemoglobin, can serve as an absolute indicator of transfusion need. However, the use of a physiologic value in conjunction with clinical assessment of the patient status would permit a rational decision regarding the appropriateness of transfusion before the onset of hypoxia or ischemia.¹⁸⁶

Literature on mortality in surgical patients refusing transfusion provides insight into the circumstances in which transfusion may be of benefit. In a review of 16 reports of the surgical outcomes in Jehovah's Witness patients who underwent major surgery without blood transfusion, mortality associated with anemia occurred in only 1.4% of the 1,404 operations.¹⁸⁷ A more detailed analysis of 61 studies of Jehovah's Witness patients found that, with the exception of three patients who died after cardiac surgery, all deaths attributed to anemia occurred in patients with hemoglobin ≤ 5 g/dl.¹⁸⁸ In one large study of surgical patients refusing transfusion, the risk of death was found to be higher in patients with cardiovascular disease than in those without.¹⁸⁹ A subsequent analysis¹⁹⁰ found that although the risk of death was low in patients with postoperative hemoglobin levels of 7.1 to 8.0 g/dl, morbidity occurred in 9.4%; the odds of death in patients with a postoperative hemoglobin level ≤ 8 g/dl increased 2.5 times for each gram decrease in hemoglobin level.¹⁹⁰

A large retrospective study of elderly patients who underwent surgical repair of hip fracture found that transfusion of patients with hemoglobin levels ≥ 8 g/dl did not influence 30-day or

P.558

90-day mortality.¹⁹¹ This was confirmed by a subsequent¹⁹² randomized, prospective study. Prospective, randomized trials in patients undergoing cardiac surgery¹⁹³ and receiving critical care¹⁹⁴ have each demonstrated that such patients can tolerate anemia without transfusion to hemoglobin levels between 7 and 8 g/dl, with equivalent clinical outcomes comparable to patients maintained at hemoglobin levels of greater than 10 g/dl. A Cochrane meta-analysis of prospective

randomized trials comparing “high” versus “low” hemoglobin thresholds on more than 3700 patients¹⁹⁵ found that a hemoglobin of 7 g/dl was sufficient for the majority of patients.

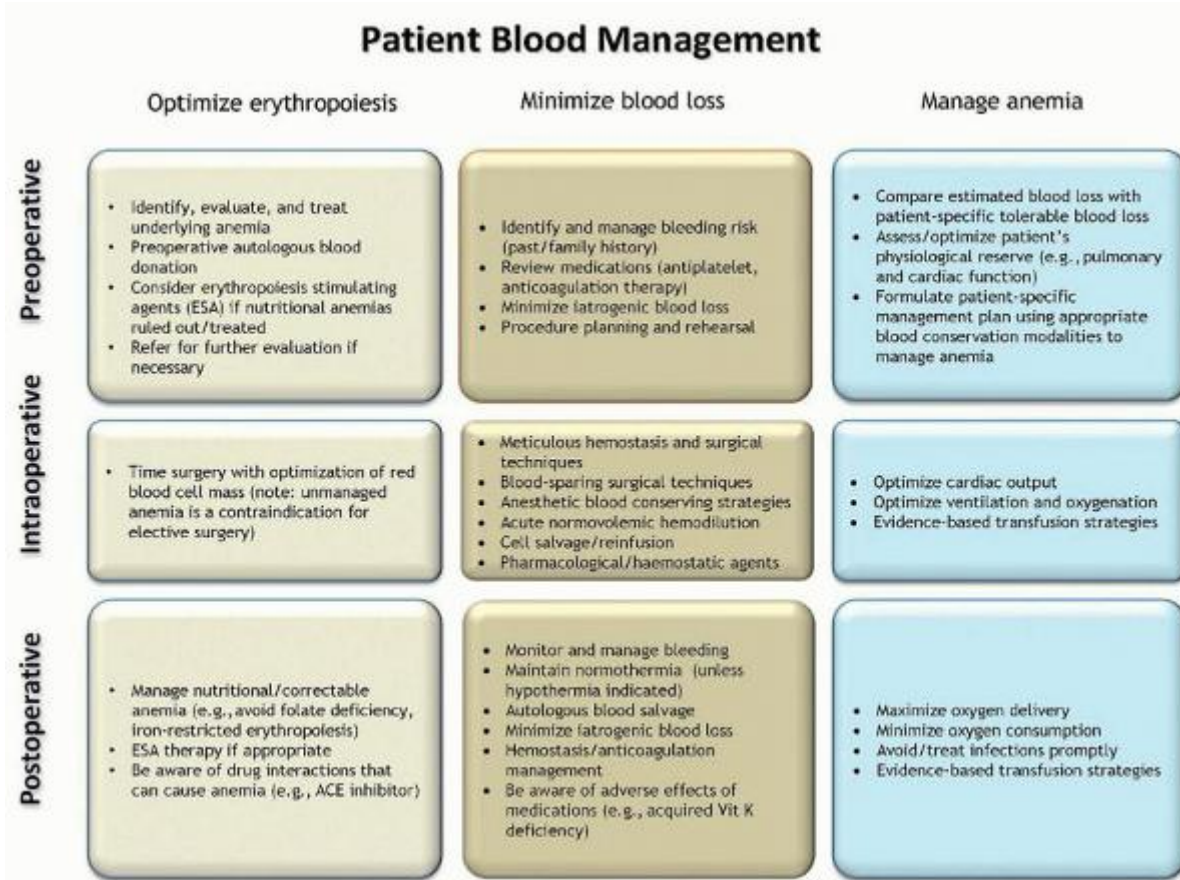

FIGURE 21.2. Patient blood management. These principles applied in the perisurgical period enable treating physicians to have the time and tools to provide patient-centered evidenced-based patient blood management in order to minimize allogeneic blood transfusions. (From Goodnough LT, Shander A. Patient blood management. *Anesthesiology* 2012;116:1367-1376, with permission.)

AABB clinical practice guidelines suggest that patients should not be transfused with red blood cells, in the absence of symptoms/signs of anemia, unless the Hgb concentration is less than 7 to 8 g/dl, or less than 8 g/dl for patients with symptoms or known to have cardiovascular disease.¹⁹⁶ Comprehensive blood management guidelines from the Societies of Thoracic Surgeons and Cardiovascular Anesthesiologists contain similar recommendations, suggesting that RBC transfusion may be life-saving when hemoglobin is less than 6 and is reasonable in most patients when hemoglobin is less than 7.¹⁹⁷ However, it is unlikely that a hemoglobin value alone should serve as a “transfusion trigger;” patients should be managed, rather than laboratory values.¹⁹⁸

Red Cell Transfusion in Specific Settings

Massive Hemorrhage

One of the major indications for blood transfusion is the restoration of circulating blood elements after the loss of large amounts of blood (Table 21.2).¹⁹⁹ In general, adults who lose <20% of their blood volume (or approximately 1 L) do well without red cell transfusion, providing that fluid resuscitation is adequate to maintain the circulating blood volume and that further blood loss is avoided. Young healthy patients can sustain losses of up to 30% to 40% of blood volume as long as intravascular blood volume is adequately maintained with intravenous (IV) fluids.

Massive hemorrhage is generally defined as transfusion of more than 10 U of RBC (one complete blood volume replacement) within 24 hours. Massive hemorrhage is a common complication in a number of clinical settings. In traumatic injury, hemorrhage is a major cause of morbidity and is responsible for almost 50% of deaths occurring within 24 hours of injury and up to 80% of intraoperative trauma mortalities.^{200,201} and ²⁰² In addition, cardiovascular and hepatobiliary procedures can frequently result in massive bleeding^{203,204}; postpartum hemorrhage events can complicate

labor and delivery; and diverticulosis or varices can lead to significant gastrointestinal bleeding.^{204,205,206} and ²⁰⁷ Blood component support before and after control of massive hemorrhage is critical in these

P.559

scenarios.²⁰⁶ Despite the need for consensus on the management of patients with massive bleeding, currently no such consensus exists.

TABLE 21.2 CLINICAL SIGNS OF BLOOD LOSS

Volume Lost		Clinical Signs
ml	% of Blood Volume	
500	10	None; occasionally vasovagal syncope
1,000	20	At rest, there may be no clinical evidence of volume loss; a slight postural drop in blood pressure may be seen; tachycardia with exercise
1,500	30	Resting supine blood pressure and pulse may be normal; neck veins flat when supine; postural hypotension
2,000	40	Central venous pressure, cardiac output, systolic blood pressure below normal even when supine and at rest; air hunger, cold clammy skin; tachycardia
2,500	50	Signs of shock; tachycardia, hypotension, oliguria, drowsiness, or coma

An estimated 10% of military trauma patients and 3% to 5% of civilian trauma patients receive massive transfusions (MTs).^{205,208,209} Within the standard definition of massive hemorrhage there appears to be an important subset of patients who may benefit from blood components in addition to RBCs, specifically, those with rapid massive bleeding.²¹⁰ Both Moore et al.²¹⁰ and Holcomb et al.²⁰⁵ demonstrated that patients receiving 10 U of RBCs in the first 6 hours after injury had a higher rate of mortality than those receiving the same quantity of RBCs over a 24-hour period. Early identification of this patient population and specific massive transfusion (MT) support strategies involving multiple blood components have been associated with improved survival.²¹¹

In response, transfusion services have implemented protocols to quickly and efficiently provide packages of blood products to patients with massive hemorrhage. There are a number of criteria available to help evaluate the effectiveness of different strategies used by transfusion services. Evaluation of the effectiveness of these protocols should include several parameters: clinical outcomes (survival, length of hospital stay, multisystem organ failure, infection rate, etc); post-resuscitation laboratory parameters (hemoglobin, prothrombin time [PT], partial thromboplastin time [PTT], fibrinogen, and PLT count); and 24-hour blood component and crystalloid use. A recent review summarizes the literature to date, highlights some of the limitations of the available evidence, and identifies areas in need of additional study.²¹²

Recent data from the US Army's Institute of Surgical Research have shown improvement in outcomes when soldiers requiring MTs received resuscitations with ratios of component types that were similar to whole blood transfusions.^{213,214} Subsequent reports, primarily in the military literature, further support a component therapy transfusion in ratios of 1 U RBC/1 U plasma/1 random donor unit of PLTs.^{205,215,216} and ²¹⁷ However, these are retrospective studies, with a survivorship bias.^{205,215,216} and ²¹⁷ The military data also lack adjustment for confounding variables such as injury severity.^{205,215,216} and ²¹⁷ Nevertheless, these data have led to widespread support of this ratio, particularly the 1:1 ratio of RBC/plasma, although considerable debate remains on this topic.^{218,219} and ²²⁰

Civilian trauma studies have also evaluated the impact of more aggressive ratios and noted an association with improved survival with use of MT protocols.^{221,222,223} and ²²⁴ Similar to the military data, such studies also support using a more aggressive RBC/plasma ratio, reporting a significant reduction (41% vs 62%) in 30-day mortality as compared with those that received less plasma.²²⁵ This was independent of age and Trauma Related Injury Severity Score, which by themselves were independent predictors of mortality.²²⁵

Several studies have called into question the benefit of higher plasma ratios.^{223,226} Nevertheless, the cumulative data appear to support early, proactive support with high ratios of plasma to RBC along with additional support with platelets.^{218,219} Not all studies showed a mortality benefit, and in the absence of randomized trials, data to convincingly support a particular ratio or formula are needed. However, the existing data suggest that a well-organized MT protocol

that is activated in a timely fashion is likely to demonstrate improved patient outcomes and result in less overall blood product usage in large trauma centers.^{218,219}

Elective Surgery

In preparation for surgery, preoperative requests for typed and crossmatched blood should be based on the predetermined likelihood of a procedure requiring a blood transfusion. "Maximum surgical blood order schedules" or "standard blood orders" specify the number of units that should be crossmatched for a variety of procedures and include guidelines for pretransfusion assessment.^{227,228} A pretransfusion request for type and crossmatch should be sent to the blood bank if it is likely ($\geq 10\%$ probability) that blood will be required for a specific surgical procedure. The request should be for a type and screen if it is unlikely ($< 10\%$) that the patient will require blood. As discussed previously under patient blood management, preoperative evaluation and management of anemia to correct deficits in red cell mass is the single most important determinant of the likelihood of perioperative blood transfusions.¹⁷²

Nutritional Deficiencies and Other Anemic States

RBCs are often transfused in the management of various types of anemia. Published guidelines (see above) advise transfusing on the basis of clinical indications. Physiologic adaptations to anemia, including elevated red cell 2,3-DPG content and increased cardiac output, compensate to preserve oxygen transport and delivery to a significant extent in chronic anemias. Transfusion is rarely indicated in these patients if there is time to correct anemia with alternative therapies.

Patients who are anemic solely because of deficiency of iron, folate, or B₁₂ rarely require transfusion. Patients with "lifethreatening" anemia (Hgb < 6.5 g/dl) by WHO (World Health Organization) and NCI (National Cancer Institute) criteria may require transfusion.²²⁹ Elderly patients who present with pernicious or severe iron deficiency anemia may require red cell transfusion, particularly when angina or congestive heart failure has been the cause of the patient seeking medical attention. Iron-deficient patients who are also bleeding actively (e.g., from the gastrointestinal tract) may also require red cell transfusion. In such situations, the goal of transfusion is not to correct the patient's hemoglobin concentration, but to raise it sufficiently to stabilize the patient until specific therapy can be administered.

Hemolytic Anemias

Patients with acute or chronic hemolytic anemias may require red cell transfusion; often, this need arises at the time of a hemolytic or aplastic crisis. Such patients are often critically ill, and safe transfusion requires careful clinical attention. In autoimmune hemolytic anemia,^{230,231} the clinician may be faced with a severely anemic patient for whom crossmatch-compatible blood cannot be obtained. These patients produce an antibody that

P.560

reacts with all RBCs including their own, and the transfusion of serologically incompatible red cells may be necessary. At a hemoglobin < 6 g/dl, most patients require transfusion. In these cases, withholding transfusion in the absence of "compatible" RBCs places the patient in needless danger. Although "incompatible" cells will have a shorter than normal lifespan, transfusion reactions are infrequent. The risk of complications is increased if the patient has brisk hemolysis and a large volume of blood is infused, or if the patient has an undetected alloantibody in addition to the autoantibody. If time allows, special techniques should be used to evaluate these patients for alloantibodies prior to transfusion (see "Autoagglutination"). Consultation with a transfusion medicine specialist is recommended in these cases.

Hypoproliferative Anemias

In aplastic and sideroblastic anemias, myelodysplastic states, and myelofibrosis, patients often depend on regular transfusion of red cells and may die of transfusion-induced iron overload after several years of such support unless precautions are taken to remove iron. The development and use of erythropoiesis stimulating agents have reduced the need for transfusion in many patients with hypoproliferative anemia, such as those with end-stage kidney disease (see Chapter 41) and in patients with chemotherapy-induced anemia.²³²

Hereditary Red Cell Disorders

In children with thalassemia (see Chapter 34), bone marrow hyperplasia with its undesirable effects on the skeleton may be ameliorated, and iron absorption decreased, by regular transfusions to maintain a near-normal hemoglobin concentration.²³³ Such a program is possible only in conjunction with an aggressive iron chelation program, as the iron load otherwise leads to fatal hemosiderosis. In patients with sickle cell disease and vaso-occlusive crises (see Chapter 33), the adverse microvascular effects of sickle cells can be relieved temporarily by hydration with crystalloid therapy to

restore intravascular volume, rather than with RBC transfusions (to avoid chronically unnecessary risks of alloimmunization and iron overload). Red cell exchange may be indicated when impaired oxygenation leads to <90% O₂ saturation, in order to address the generation of sickle cells in acute chest syndromes. A multicenter trial (STOP trial) showed a significant decrease in the incidence of stroke in patients with abnormal transcranial Doppler studies who were treated with simple or exchange transfusions to maintain their hemoglobin S concentrations <30%, compared to patients who remained on standard supportive care with transfusion only when clinically indicated.²³⁴

Pretransfusion Testing of Red Cells

Compatibility Testing Process

The process of selecting red cells for transfusion involves three stages. Blood grouping involves determination of the ABO group and Rh type of both recipient and donor specimens. The recipient's serum or plasma is screened for the presence of unexpected red cell antibodies. Crossmatching, either serologically or electronically, after selection of a donor unit of the appropriate group and type determines whether the donor cells are compatible with the recipient's plasma.

Properly selected blood products will be compatible with the recipient, indicating that transfusion should not result in hemolysis of donor red cells. Because only the ABO and Rh(D) red cell antigens are prophylactically matched in routine transfusion practice, there are always significant antigenic differences between donor and recipient, both for red cells and for the accompanying leukocytes, platelets, and plasma. Repeated exposure to foreign antigens with chronic transfusion or pregnancy may result in antibody formation in the recipient.

There is no room for error in the provision of blood for transfusion. If clerical or laboratory error results in donor and recipient being mismatched for the ABO group, transfusion of even a few milliliters of red cells may lead to a life-threatening transfusion reaction with shock, intravascular coagulation, and acute renal failure. Such reactions are uncommon because of rigid adherence to a routine designed to maximize safety at all levels of the transfusion process; however, with the decrease in the risk of transfusion-transmitted infections, such reactions are becoming one of the leading risks of transfusion.^{166,235} Careful identification of the patient for whom the blood is ordered, including complete labeling of the specimen at the bedside of that patient, is essential. Careful ABO blood grouping along with comparing results of ABO testing with historical records for each patient adds to the level of safety. Ensuring positive identification of crossmatched units of blood and verifying that the information identifying the unit with the intended recipient is reviewed in the presence of that recipient before the administration of the blood are crucial.^{2,5}

Blood Grouping

The presence of ABO antigens is determined by testing the unknown RBCs with anti-A and anti-B sera by one of a variety of methods including slide, tube, gel, or microplate tests.² Identifying which ABO antigens are on the surface of an individual's RBCs is called the forward grouping or forward typing. Cells agglutinated only with anti-A serum are group A; those reacting only with anti-B are group B. Those reacting with both antisera are group AB, and red cells that fail to agglutinate with either anti-A or anti-B are group O.

“Reverse grouping” or “reverse typing” should be performed to confirm the reaction obtained by the forward grouping test. This involves testing the reactions of the serum or plasma from the person of unknown type with reagent red cells of known A and B type. Agglutination of the red cells indicates the presence of anti-A or anti-B in the individual's serum. The conclusions of forward and reverse tests should agree as shown in Table 21.3.

The antisera used in blood group antigen detection can be obtained from donors with naturally occurring high levels of antibodies, from people or animals specifically stimulated to produce antibodies against blood groups, or from monoclonal antibodies of mouse or human origin. The advantages of monoclonal antibodies include their high quality and stability and their ease of production in large quantities. Antisera must be of known specificity and potency, and control testing must be done on a routine basis.²

The Rh type of red cells is determined by examining the cells' reaction with anti-D serum from commercial sources. Commercial

P.561

antisera may be modified by the manufacturer with the addition of high concentrations of protein or by chemically altering the immunoglobulin (Ig) G molecules in such a way that they perform as direct agglutinins in the laboratory. This permits rapid, reliable testing to determine the D antigen status of the cells. However, these high-protein reagents may cause false positive reactions because of spontaneous aggregation of some red cells in their presence. If this happens, an

Rh-negative patient could be typed as Rh-positive if the recommended Rh control is not tested simultaneously. This problem has led to the development of low-protein, saline-reactive monoclonal reagents. Monoclonal anti-D reagents contain both human IgM and polyclonal IgG antibodies and are currently most widely used. They can also be used in the antiglobulin test for weak D. As with all reagents, the manufacturers' instructions must be followed.²

TABLE 21.3 ABO GROUPING

Patient Blood Group	Expected Reactions of			
	Anti-A	Anti-B	A Cells	B Cells
O	None	None	+	+
A	+	None	None	+
B	None	+	+	None
AB	+	+	None	None

Red cells reacting weakly with anti-D reagents are called weak D. If donor blood is being tested, the absence of D must be confirmed. If the initial test for D is negative, a second, more sensitive test must be performed using a method that detects weak D. If D is detected by either method, the unit is labeled Rh-positive.^{2,5} In patients, testing for weak D is not required. Patients who are typed as Rh-negative, but who are really weak D-positive, will not be adversely affected by the transfusion of Rh-negative products. Patients known to be weak D-positive, however, may be given Rh-positive donor blood. Before concluding that a patient is weak D-positive, care must be taken to ensure that the patient has not recently been transfused with Rh-positive red cells or experienced a large fetal-maternal hemorrhage.

Testing for Red Cell Antibodies

Antibodies in potential blood transfusion recipients fall into several categories. The most common blood group antibodies that are clinically significant and may be implicated in hemolytic transfusion reactions or hemolytic disease of the newborn are shown in Table 21.4.

TABLE 21.4 SIGNIFICANCE OF CERTAIN BLOOD GROUP ANTIBODIES

Blood Group System	Antibody	Relative Frequency in Antibody Screening	Clinical Significance	
			Hemolytic Transfusion Reaction	Hemolytic Disease of the Newborn
ABO	Anti-A	All group B and O	Yes	Yes
	Anti-B	All group A and O	Yes	Yes
Rhesus	Anti-D	Common	Yes	Yes
	Anti-c	Common	Yes	Yes
	Anti-E	Common	Yes	Yes
	Anti-C	Common	Yes	Yes
	Anti-e	Uncommon	Yes	Yes
Kell	Anti-K	Common	Yes	Yes
	Anti-k	Rare	Yes	Yes
Kidd	Anti-Jka	Common	Yes	Yes
	Anti-Jkb	Rare	Yes	Yes
Duffy	Anti-Fya	Common	Yes	Yes
	Anti-Fyb	Uncommon	Yes	Yes

MNS	Anti-M	Common	Rare	Rare
	Anti-N	Rare	Rare	Rare
	Anti-S	Uncommon	Yes	Yes
	Anti-s	Rare	Yes	Yes
Lewis	Anti-Lea	Common	Yes	No
	Anti-Leb	Uncommon	No	No
P	Anti-P1	Common	Rare	No
Ii	Anti-I	Uncommon	No	No

All human plasmas contain naturally occurring antibodies that react with the complementary antigens of the ABH system. These are of great importance in transfusion, as they are complementfixing IgM antibodies; transfusion of incompatible red cells leads to immediate hemolytic reactions. Many people also have naturally occurring antibodies (usually low-titer IgM antibodies reacting at or below room temperature) that react with some antigens of the Lewis, P, Ii, MN, or other systems; these are rarely active above room temperature and are only occasionally important in transfusion. Finally, people exposed to foreign red cells by prior transfusion or pregnancy may produce IgG antibodies to antigens of certain other systems, primarily Rh (C, c, D, E, e), Kell, Duffy, Kidd, and Ss, but many less common possibilities exist. These red cell antibodies are clinically significant. They do not often lead to intravascular hemolytic reactions, but transfused incompatible red cells may exhibit decreased survival caused by increased clearance in the reticuloendothelial system. Many of these IgG antibodies can also cause hemolytic disease of the fetus and newborn.^{2,236}

There are two major classes of antibodies that react with red cells. Complete or saline antibodies agglutinate red cells suspended in saline solution; these are usually IgM. Antibodies that do not react visibly in saline and are capable of producing agglutination reactions only with special techniques to make their interaction with red cells detectable are called incomplete agglutinins; these are generally IgG antibodies.

The best example of a room temperature saline agglutination test is that used in ABO grouping. Other red cell antibodies that are readily detected in saline suspension are those belonging to

P.562

the Lewis, MN, P, and Ii blood group systems. With the important exception of ABO system antibodies, many of the others detected with this test are of no clinical significance, as they are not reactive at 37°C.

The best examples of incomplete agglutinins, or IgG antibodies, are those that react with antigens of the Rh system. If such antibodies are not detected in the recipient, immediate hemolysis of transfused, incompatible red cells is extremely rare. However, their presence may lead to a significantly decreased survival of transfused cells and the development of an extravascular hemolytic syndrome (delayed hemolytic transfusion reaction [DHTR]).

Antiglobulin Test

The antiglobulin (Coombs) test (Figs. 21.3 and 21.4) is based on the reaction between an antihuman globulin (AHG) reagent and antibody- or complement-coated red cells. AHG reagents are commercially available and are prepared either by the injection of an animal with human globulin or through hybridoma technology. AHG reagents may be polyspecific or monospecific. The polyspecific reagents contain antibodies with both antihuman IgG and anticomplement activity. Monospecific AHG reagents, anti-IgG, anti-C3b, and anti-C3d, are used to determine which protein is responsible for a positive direct antiglobulin test.²

The direct antiglobulin test is performed by washing the patient's cells with saline, adding polyspecific AHG, and observing for agglutination (Fig. 21.3). Positive reactions (agglutination) suggest the presence of IgG antibodies or complement bound to the red cell.² The indirect antiglobulin test is used to determine the presence of red cell antibodies in serum or plasma (Fig. 21.4). Reagent red cells are incubated with the patient's serum or plasma, washed to remove unbound immunoglobulins, mixed with AHG (usually monospecific anti-IgG), and then centrifuged briefly. The cell button is gently resuspended and examined for agglutination. A positive reaction suggests that IgG antibodies in the patient's plasma have bound to the reagent cells. A positive indirect antiglobulin test therefore indicates the presence of antibodies capable of reacting with red cells and possibly capable of hemolyzing such cells if they were transfused.

Direct and indirect antiglobulin tests are the simplest approaches to the detection of IgG anti-red cell antibodies. Because many of these serologic reactions are rather weak, the addition of various media has been used to enhance the agglutination reaction. These tests involve procedures that diminish the mutually repulsive electrostatic forces between red cells, permitting visible agglutination by IgG antibodies.² Antigens that often require such enhancing tests include those of the Kidd (Jk^a and Jk^b), Rh (D, C, E, c, e), Kell, and Duffy (Fy^a and Fy^b) systems.

FIGURE 21.3. Direct antiglobulin test with anti-immunoglobulin G (IgG) and anti-C3d. RBC, red blood cell. (Reprinted from Jeter EK, Spivey MA. Pretransfusion testing. In: Jeter EK, ed. Introduction to transfusion medicine: a case study approach. Bethesda, MD: American Association of Blood Banks Press, 1996;56, with permission.)

Media That Enhance Agglutination

Adding albumin, low-ionic-strength saline (LISS) or polyethylene glycol (PEG) solutions to antibody identification tests can enhance the sensitivity of the test system.²³⁷ These solutions augment the antibody-antigen interaction in a variety of ways, enhancing the detection of weak or otherwise undetectable antibodies. Treating reagent red cells with proteolytic enzymes such as papain or ficin also increases the sensitivity for some antibodies such as those reacting with Rh and Kidd system antigens. These enzyme reagents weaken or destroy other red cell antigens (M,N,Fy^a, Fy^b, and, in some cases, S, s)—a trait that can be helpful in the identification of multiple red cell antibodies in a single serum sample.²

Other Antibody Identification Tests

Sera containing several antibodies may be analyzed by absorbing with one or more selected red cells.^{2,236} Antibodies so adsorbed may be eluted from the cells, and their specificity may be determined. Alternatively, the specificity of antibodies not adsorbed and remaining in the supernatant can be identified. When necessary, the identity of certain antibodies may be confirmed by their inhibition by soluble antigens, such as A, B, and Lewis substances present in the saliva of secretors. Neonatal (cord) red cells exhibit a number of antigens very weakly and may be used to investigate antibody specificity.

Selection of Red Cells for Transfusion

A series of serologic tests is used to select donor blood for patients. Although individual transfusion services prefer different specific methods, the general principles of compatibility testing are the same.

A properly labeled, fresh sample of patient blood must be provided. If the patient has been transfused or has been pregnant within the preceding 3 months, the specimen must be obtained within 3 days of the anticipated transfusion.⁵

Donor

The ABO group of the donor unit must be confirmed. The donor unit Rh typing must also be repeated if the unit is labeled as Rh-negative. These tests are performed to confirm the blood group and to ensure that the unit has not been mislabeled.

Recipient

The recipient's ABO group and Rh type must be determined. The recipient's serum is screened for the presence of antibodies that may have been induced by prior pregnancy or transfusion. A set of commercially prepared group O red cells, expressing 18 clinically relevant antigens (D, C, E, c, e, M, N, S, s, P₁, Le^a, Le^b, K, k, Fy^a, Fy^b, Jk^a, and Jk^b), is used in this test in accordance with FDA rules. The use of group O reagent red cells avoids agglutination by anti-A or anti-B. These reagent cells are incubated with the patient's serum and tested with the indirect antiglobulin test for reactions indicating the presence of antibody in the serum.²

If such screening reactions are positive, the antibody specificity can be determined by reaction of the serum with a commercially prepared panel of reagent red cells of known antigenic composition. If an antibody has been found on the screen and the patient's clinical status allows, it is best to withhold transfusion until identification is complete. The incidence of unexpected RBC antibodies in patients requiring transfusion is low.^{238,239}

Type and Screen

If it is unlikely that blood will be required, for example, for a surgical procedure with <10% likelihood of transfusion, a “type and screen” rather than a crossmatch should be requested. In this instance, the blood bank types the patient's blood and screens for unexpected antibodies; if antibodies are not found, the blood bank ensures that blood of the appropriate group is available for transfusion if necessary. In such an event, a telephone call can trigger a rapid crossmatch test and blood will be available with minimal delay. The appropriate use of type and screen improves the efficiency of the blood bank. It assists in inventory control by not segregating blood for patients who are unlikely to require it and is therefore more cost-effective.

Crossmatch

If no antibody has been detected on the screen and there is no record of the previous presence of a clinically significant antibody, only verification of ABO compatibility between the donor unit and recipient is required before transfusion. This can be done either by an immediate spin crossmatch or a computer crossmatch.

The immediate spin crossmatch consists of mixing the patient's serum with donor saline-suspended red cells at room temperature, spinning the tube, and reading the results immediately. The purpose of this test is to detect ABO incompatibility due to the presence of anti-A, anti-B, or both, in the patient's serum.²

The conditions for computer or “electronic” crossmatch are outlined in the AABB standards.⁵ Briefly, the computer system must be validated to prevent release of ABO-incompatible blood. This computer crossmatch can be used only for patients who do not have a record of clinically significant antibodies. The recipient's ABO blood group must have been determined

on at least two separate tests. The system must contain complete information on the donor unit and the recipient, including ABO group and Rh type. Data entered must be verified as correct before the release of blood. The system must contain logic to alert the user to discrepancies for either the donor unit or the recipient, including unit labeling, blood grouping, and ABO incompatibilities.

If a clinically significant red cell antibody has been found when a patient's plasma or serum is screened for unexpected antibodies, antibody identification should be performed. Once the antibody specificity has been identified, donor units that lack the corresponding antigen should be selected, and a crossmatch using an indirect antiglobulin test should be performed on each unit to ensure compatibility. The physician should also be advised about the nature of the problem, as well as the potential for delays if further units are required.

Once a unit of blood is crossmatched for a patient, there must be positive identification of the patient and the blood product both in the laboratory before release of a blood product to the nursing ward as well as at the patient's bedside by the transfusionist. Before every transfusion, the requisition, the label on the blood product, and the patient's identification must be checked. These aspects of patient and blood product identification are critical safety steps and must be documented.⁵

Uncrossmatched Blood for Emergency Transfusion

For patients in hemorrhagic shock, it is necessary to transfuse blood immediately, and no blood bank testing should be attempted before emergency transfusion. The risk of transfusing group O "uncrossmatched" red cells is extremely low and is certainly much lower than the risk of the patient's death if blood transfusion is delayed. If a patient is to be given uncrossmatched blood, a specimen of the patient's blood should be obtained prior to transfusion so that typing and screening can be performed while the transfusion is proceeding.

Once the patient's blood group has been determined, ABO group-compatible uncrossmatched blood may be used.⁵ Until the patient's Rh type is determined, uncrossmatched blood should be Rh(D)-negative when used in women of childbearing age, in whom sensitization to D would be undesirable. As Rh-negative blood is often in limited supply, Rh-positive blood is often used for emergency transfusion of older females and of males of unknown blood group. In such cases, sensitization may occur, but the risk of an immediate hemolytic reaction is low.²³⁶

Despite the lack of a crossmatch, transfusion of group-specific blood under emergency situations is safe. The incidence of red cell alloantibodies in healthy people is low, and most such antibodies do not cause dangerous acute intravascular hemolytic transfusion reactions. However, the decision to use uncrossmatched blood is the responsibility of the attending physician, who must weigh the risks against the expected benefits and document in the patient's record the need for the uncrossmatched blood.

Table 21.5 outlines the selection of blood and plasma by ABO type. If the blood group is known, group-compatible red cells and plasma can be selected. If the blood group is not known, group O

P.564

red cells should be used; if plasma is required, group AB plasma should be used because it contains no anti-A or anti-B.

TABLE 21.5 SELECTION OF BLOOD AND PLASMA BY ABO TYPE

Component	Recipient ABO Type	Selection of Blood Component	
		Preferred	Alternate
Red blood cells	O	O	None
	A	A	O
	B	B	O
	AB	AB	A, B, O
Fresh frozen plasma	O	O	A, B, AB

Modified from Jeter EK, Spivey MA. Introduction to transfusion medicine: a case study approach. Bethesda, MD: American Association of Blood Banks Press, 1996.

Crossmatching Problems

Standard serologic techniques often depend on agglutination as an end point. There are several agglutinating phenomena that can interfere with the correct interpretation of these serologic tests and may delay antibody identification and crossmatching. Pseudoagglutination refers to red cell clumping (rouleaux formation) that typically occurs in the presence of dysproteinemias, or after the administration of dextran or hydroxyethyl starch. Dilution in saline abolishes the reaction.^{2,236} Autoagglutination refers to red cell agglutination by the patient's own serum or plasma and often indicates the presence of a cold agglutinin. Washing patient red cells with warm saline can often remove enough of the antibodies so testing can be completed.² Polyagglutination is the phenomenon in which a patient's red cells are agglutinated by most or all group-compatible sera. During bacterial or viral infections, enzymes of the infecting organism can cause alteration of antigenic structures on the red cell membrane, exposing previously hidden antigens such as T, or more rarely, Tn.²³⁶ Most adult sera contain naturally acquired antibodies capable of reacting with these determinants. The situation may be elucidated by testing the patient's red cells with cord serum, which lacks the antibodies necessary for this reaction, and by examining for reactions with plant lectins that have specific activity with the antigens involved in polyagglutination.^{240,241}

Red Cell Autoantibodies

A positive indirect antiglobulin test against all screening and donor red cells often indicates the presence of an IgG, warm-reacting autoantibody. The patient's direct antiglobulin test is also positive. Such autoantibodies may preclude the identification of any serologically compatible donor units. If red cells are transfused, it is essential that ABO compatibility be ensured. The patient's serum should be screened for alloantibodies that might be masked by the autoantibody.^{2,230,231,242,243} Such screening requires the removal of the autoantibody from the patient's serum, so that any alloantibodies present can be identified. If the patient has not been transfused within the last 3 to 4 months, this can be done by absorbing autoantibody from the serum with autologous red cells, from which already attached antibody has been removed by enzyme or chemical treatment.² Alternatively, autoantibody may be removed by absorption with a panel of cells selected to lack the antigens to which the patient may become alloimmunized. The autoantibody-depleted serum can then be examined for the presence of residual alloantibodies, and a serologic crossmatch can be done. If only the autoreactive antibody is present, transfusion of red cells is generally well tolerated.

Alloantibody to High-incidence Antigens

Occasionally, a patient may have a red cell antibody that does not react with the patient's own cells but reacts with all donor red cells. Identification of these antibodies is particularly challenging, requiring rare cells that lack common red cell antigens. Assistance of specialized laboratories may be needed both to identify the antibody to a high-incidence antigen as well as to locate compatible blood. In some of these cases, it is not clear whether the antibody is likely to cause significant hemolysis. The utilization of DNA-based methodologies to identify donors with rare blood types is a useful tool in these challenging situations.²⁴⁴

Drugs

Some drugs may stimulate an autoantibody in the patient that reacts with all reagent cells tested as well as with donor red cell units crossmatched. Drugs implicated include α -methyl dopa, levodopa, fludarabine, and procainamide.² In some cases, the *in vitro* findings may be identical to those found in autoimmune hemolytic anemias. The presence of these antibodies may or may not be clinically significant but may result in a delay if a transfusion is required. In most cases, however, drug-induced antibodies are associated with a positive direct antiglobulin test that is not part of the standard pretransfusion or crossmatch testing, and the indirect antiglobulin test is negative. The mechanisms of drug-induced hemolytic anemias are discussed in Chapter 29.

Red Cell Genotyping

The use of DNA-based methods for red cell antigen identification can assist in securing the optimal blood products for transfusion. The molecular bases for many of the major blood group antigens have been identified and DNA-based methods for their detection developed. Because these methods do not directly detect the presence of red cell antigens, challenges with widespread application still exist.²⁴⁴ When used with standard serologic testing, however, such methods are useful in identifying donors for patients with multiple red cell antibodies or blood donors with rare antigen types.

Additionally, these methods are helpful in determining a patient's red cell antigen makeup when chronically or recently transfused or when access to a blood specimen increases patient risk (e.g., fetus).

Special Considerations in Neonatal Transfusion

Pretransfusion Testing

The so-called naturally occurring IgM ABO antibodies do not begin to appear until approximately 3 to 6 months of age. However, IgG antibodies of maternal origin, including maternal anti-A or anti-B, may be passively transferred to the fetus. Thus, pretransfusion testing in the newborn consists of ABO and Rh typing of the infant's cells and an antibody screen for passively transferred maternal IgG antibodies, including anti-A or anti-B. If the initial antibody screen is negative, the infant may be transfused with products compatible with the patient's ABO/Rh type, and no further compatibility testing is required for the first 4 months of life. If a clinically significant antibody of maternal origin is detected, units that are antigen-negative or crossmatch-compatible must be issued until the antibody is no longer detectable in the infant's serum.⁵

Selection of Products for Neonatal Transfusion

Preterm infants may require multiple transfusions to replace blood drawn for laboratory tests. It has become common practice to limit donor exposure by reserving one unit or one half unit for a single preterm infant. Serial aliquots may be obtained using a sterile connection device up to the outdate of the unit.^{245,246,247} Blood products for low-birth-weight infants should be irradiated to prevent transfusion-related GVHD and should be CMV reduced risk (i.e., CMV antibody negative and/or leukoreduced). Either CPDA-1 or additive red cells may be used for aliquot transfusions. However, the safety of additive solutions has not been demonstrated in the setting of massive transfusion of infants (i.e., one unit or more in a neonate). The amount of free potassium in the supernatant of the irradiated blood may also become clinically important in the setting of massive transfusion.¹³² For massively transfused infants at increased risk of hyperkalemia, the dose of free potassium in the red cell product may be decreased by delaying irradiation until just before issue or by washing the RBCs.

Exchange Transfusion

The most common indication for exchange transfusion in the neonate is hyperbilirubinemia that has not responded adequately to

P.565

phototherapy, particularly that associated with hemolytic disease of the newborn. Usually, one to two blood volumes are exchanged.

Red cells collected in CPD or CPDA-1 that are less than 1 week old are preferred. Because several clotting factors in newborns are at the low end of hemostatic levels, many centers perform exchanges using whole blood, or red cells reconstituted with plasma, to prevent further lowering of factor levels by the exchange. Red cells used for the exchange transfusion should be irradiated to prevent transfusion-related GVHD.²

Administration of Blood

The first step before the administration of blood or of a blood product is to obtain consent for the transfusion from the patient. Every hospital should set its own policy. A note in the chart indicating that the risks of transfusion as well as the indications and alternatives have been discussed with the patient and that the patient has accepted this form of therapy may be adequate, depending on applicable laws and regulations. There must be a written order for the administration of the product.⁵

All blood products should be given through an appropriate blood administration set containing a filter; careful aseptic technique should be practiced at all times. There must be confirmation and documentation that the information identifying the blood product with the patient has been verified in the presence of the patient.⁵

Vital signs should be documented before and after transfusion and as clinically required. For the first 15 minutes after the infusion has begun, the patient should be kept under close observation to detect any signs of a serious transfusion reaction. If none is observed, the infusion rate may be increased. One unit of red cells is often given in 1 to 4 hours, depending on the amount to be transfused and on the patient's cardiovascular status. Infusion of a unit for longer than 4 hours is not recommended, as there is a risk of bacterial proliferation because the opened unit is at room temperature. Normal (0.9%) saline, 5% albumin, or ABO-compatible plasma may be added. No other solution and no medication should be added to or infused through the same tubing as a blood product unless there is documentation of compatibility or FDA

approval.⁵ Dextrose causes red cells to agglutinate or hemolyze; hypotonic saline causes hemolysis. Ringer's lactate or other solutions containing calcium must never be added to a blood product because the calcium present leads to coagulation. After the transfusion has been completed, the transfusion tag or record should become part of the patient's chart.

When the patient being transfused is in severe congestive heart failure, additional measures should be taken. Administration of diuretics before or during the transfusion may not be adequate to prevent aggravation of heart failure by volume overload. In the presence of heart failure, transfusion should proceed slowly (e.g., 1 ml/kg/h) with careful observation and additional diuretics given if clinically indicated. If slower rates than this are needed, the blood component may be divided by the blood bank into two or more parts and each part transfused over 4 hours. The unused portions should be kept in the blood bank until needed for transfusion.

PLATELET TRANSFUSION

Platelet transfusion may be life-saving when hemorrhage is caused by thrombocytopenia. Modern treatment for hematologic malignancies would not be possible without the ability to prevent or treat thrombocytopenic bleeding. Similarly, many surgical procedures would not be feasible without platelet transfusions. Whether this therapeutic modality is effective depends on recipient factors, such as the presence of sepsis, azotemia, drugs, and platelet antibodies, and on the ability of the blood bank to provide functional platelets in sufficient numbers.^{93,248,249}

Administration of Platelets

Platelet concentrates may be provided by the blood bank in their individual plastic bags or pooled before transfusion. Apheresis platelets do not require any preparation. Once the blood bag is opened by puncturing one of the sealed ports, the platelets must be administered within 4 hours.⁵ Platelets must be administered through a filter approved for platelet use, either a standard 170- μ m filter or a leukoreduction platelet filter.

Dosage and Expected Response

The usual dose of platelets is one unit for each 10 kg body weight, or approximately six units (or one apheresis platelet) for a typical adult dose.²⁵⁰ The in vivo recovery of transfused platelets should be assessed by a platelet count obtained 10 minutes to 1 hour posttransfusion.^{251,252}

As noted earlier, even under ideal circumstances, only two thirds of transfused platelets are expected to be found in the circulation of the recipient. One can estimate the maximum expected increase in circulating platelet count after transfusion of one apheresis platelet product containing the minimum of 3×10^{11} platelets into a 70-kg adult with a blood volume of 5 L as follows: Maximum increase in count = $2/3 \times 3 \times 10^{11}$ platelets distributed in 5 L blood volume = $40 \times 10^9/L$.

In practice, the observed posttransfusion platelet recovery in patients is often much lower than ideal. Hematology patients typically achieve an increment of approximately $20 \times 10^9/L$, about 50% of ideal, after infusion of 3×10^{11} platelets.²⁵³ A recovery as low as 30% of the ideal is generally considered "acceptable."²⁵⁴ This would correspond to an increase in platelet count of approximately $13 \times 10^9/L$ after transfusion of one apheresis platelet product to a 70-kg adult. The expected and "acceptable" increases in platelet count would be proportionately lower in a larger adult and higher with transfusion of a larger dose of platelets.

Many investigators have assessed the acceptability of a posttransfusion platelet increment by calculating a corrected count increment (CCI). With the CCI, the measured increment in circulating platelet count is corrected for the patient's size and for the dose of platelets given as follows: $CCI = (\text{posttransfusion count} - \text{pretransfusion count}) \times \text{body surface area (m}^2\text{)}/\text{number of platelets administered (}10^{11}\text{)}$.

The maximum achievable CCI is approximately $25 \times 10^9/L$. The typical CCI in patients is approximately one half of this, and the lowest "acceptable" CCI is considered to be approximately $7.5 \times 10^9/L$.^{251,254} Patients with in vivo recoveries or CCIs lower than acceptable values should be evaluated for causes of platelet refractoriness such as an enlarged spleen or alloimmunization (as discussed in the section, "Platelet Refractoriness and Alloimmunization").

In healthy adults, the half-life of transfused platelets is 3 to 5 days.⁸³ In thrombocytopenic patients, however, platelet survival is reduced. A fixed rate of platelet consumption of $7.1 \times 10^9/L/\text{day}$ has been measured in otherwise stable patients with severe thrombocytopenia.²⁵⁵ It is assumed that this platelet consumption is associated with maintenance of vascular integrity. The rate of consumption may be higher in critically ill patients.

Given the limited absolute increase in platelet count achieved with the standard dose of platelets and the presence of ongoing platelet consumption, many patients return to their baseline platelet count within 1 to 2 days of platelet

transfusion.²⁴⁹ In stable patients, the transfusion-free interval may be increased by administering larger doses of platelets with each transfusion.^{256,257} However, this strategy can result in an increase in the total number of platelets transfused.²⁵³

Indications for Platelet Transfusion

The risks of posttraumatic and spontaneous bleeding increase as the platelet count falls. In general, assuming that platelet function

P.566

is normal, there is minimal risk of spontaneous bleeding due to thrombocytopenia at platelet counts $>50 \times 10^9/L$, and this level is usually sufficient to permit surgical procedures.²⁵⁸ As the count falls below this level, there is an increasing risk of microvascular bleeding, characterized by petechiae, ecchymoses, oozing at venipuncture and incision sites, epistaxis, menorrhagia, gastrointestinal bleeding, or intracranial hemorrhage.

The precise degree of bleeding risk at any given platelet count is difficult to determine, as many other clinical variables have important effects. These include the cause of thrombocytopenia; the duration of thrombocytopenia; the nature of concurrent disease processes including sepsis, uremia, vasculitis, or malignant processes invading blood vessels or other organs; the coexistence of coagulopathies, such as liver disease, vitamin K deficiency, intravascular coagulation, or heparin treatment; and the presence of drugs such as ASA or semisynthetic penicillins that interfere with platelet function.²⁵⁹

In general, the risk of significant spontaneous hemorrhage increases gradually as the platelet count drops to $<50 \times 10^9/L$ ²⁶⁰ and is high at counts $<5 \times 10^9/L$ ^{248,249} (Figs. 21.5 and 21.6).

Clinical practice guidelines,^{258,261,262} and a Cochrane metaanalysis²⁶³ for platelet transfusion therapy have been published. Additionally, a Performance Indicator for prophylactic platelet transfusions has been developed by The Joint Commission¹⁸¹ for patients with malignant hematologic diseases or those who undergo stem cell transplantation, in which a platelet count threshold of 10,000/mm is appropriate for prophylactic platelet transfusions.²⁶⁴

Current guidelines from the European Union and United States recommend a transfusion trigger of $10 \times 10^9/L$ for platelets transfused prophylactically.^{261,265} These guidelines are based on outcomes from four randomized clinical trials that compared prophylactic triggers of $10 \times 10^9/L$ versus $20 \times 10^9/L$ in patients with acute leukemia and in autologous and allogeneic hematopoietic stem cell transplant recipients.^{264,266,267} and²⁶⁸ Two additional prospective studies also demonstrated safety with the lower threshold of $10 \times 10^9/L$ for prophylactic platelet transfusions.^{269,270} The impact of these thresholds on numbers of platelet and blood transfusions is variable, however²⁷⁰; one study demonstrated a 36% and 16% reduction in platelet and blood transfusions, respectively,²⁷⁰ while another showed no differences.²⁶⁹

FIGURE 21.5. Stool blood loss as a measure of thrombocytopenic bleeding. When stool blood loss was determined in 20 aplastic thrombocytopenic patients, blood loss was less than 5 ml/d at platelet counts $>10 \times 10^9/\text{L}$. At platelet counts between 5 and $10 \times 10^9/\text{L}$, blood loss averaged 9 ± 7 ml/d. At levels $<5 \times 10^9/\text{L}$, blood loss was markedly elevated at 50 ± 20 ml/d. (From Slichter SJ. Controversies in platelet transfusion therapy. *Annu Rev Med* 1980;31:523, with permission; and modified from Slichter SJ, Harker LA. Reprinted with permission from the *Annu Rev Med* 1980;31 by Annual Reviews, www.annualreviews.org.)

A recent trial²⁷¹ demonstrated that “low dose” prophylactic platelet transfusions are equally effective as those with “standard” or “high” dose. For therapeutic platelet transfusions, algorithms for platelet transfusions based on point of care testing have demonstrated promise in patients who have platelet-derived bleeding such as in cardiothoracic surgery^{178,272} and in trauma.²¹² Additional evidence-based studies in platelet transfusion are needed.²⁷³

Prophylactic Platelet Transfusion

Prophylactic platelet transfusion in the management of acute leukemia prevents major bleeding episodes, except perhaps during the terminal phase of the patient's illness.^{274,275} However, no difference in mortality has been demonstrated between patients transfused prophylactically and those transfused only when bleeding occurred.²⁷⁵ Despite lack of such proof, it is common practice to attempt to prevent bleeding problems by administering prophylactic transfusions to thrombocytopenic patients.

The indications for prophylactic transfusion remain controversial. Until recently, it was common practice to transfuse platelets when the count was $<20 \times 10^9/\text{L}$. A number of studies have demonstrated that reducing the trigger for prophylactic platelet transfusion from 20×10^9 to $10 \times 10^9/\text{L}$ resulted in decreased platelet transfusion without an increased frequency of significant hemorrhage. In these studies, however, the trigger for transfusion was liberalized in the presence of clinical factors suspected to increase the risk of hemorrhage, such as fever, an increased WBC count, coagulopathy, bleeding, or invasive procedures. When significant hemorrhagic events occurred, they were often in patients with morning platelet counts $>20 \times 10^9/\text{L}$.^{264,266,276} Infection, vascular lesions, or prolonged duration of thrombocytopenia may contribute to the risk of significant hemorrhage.^{266,276} Thus, it appears that a prophylactic transfusion trigger of $10 \times 10^9/\text{L}$ is as safe as one of 20×10^9 in most patients with acute leukemia or after myeloablative hematopoietic cell transplant.²⁶⁸ However, an assessment of individual clinical risk factors is appropriate.

A strategy of therapeutic-only platelet transfusions in patients after autologous peripheral blood stem cell transplantation was found to reduce platelet transfusions by one half, despite 27% of transfusions given in breach of protocol guidelines, with no difference in number of red blood cell transfusions required.²⁷⁷ Important questions remain regarding whether prophylactic

platelet transfusions are effective in reducing the risk of bleeding in clinically stable patients. A trial of prophylactic platelets study (TOPPS) versus therapeutic platelet transfusions in thrombocytopenic patients with malignancy, is currently underway in the UK.²⁷⁸

Prophylactic platelet transfusion is usually recommended before major surgical procedures in patients with platelet count $<50 \times 10^9/L$.^{250,261,279} The safety of performing surgical procedures at counts below this level has not been formally evaluated. It has been demonstrated that bone marrow aspirations and biopsies, bronchoscopies, and lumbar punctures may be safely performed in patients with platelet counts of <20 to $25 \times 10^9/L$.²⁶¹ However, the minimum safe platelet level for specific invasive procedures remains to be defined.

Prophylactic transfusion of platelets is generally not recommended in patients with platelet consumption disorders, such as idiopathic thrombocytopenic purpura (ITP) and thrombotic thrombocytopenic purpura (TTP). In ITP, there is reduced recovery and survival of transfused platelets; transfusion usually does not result in a measurable increase in platelet count. There is some evidence that platelet transfusion may be harmful in patients with TTP.^{280,281} However, platelet transfusion may be used to treat lifethreatening bleeding in patients with these disorders.²⁶²

Therapeutic Platelet Transfusion

Rapid massive bleeding is unlikely to be due solely to thrombocytopenia and suggests the presence of a vascular injury. Rapid massive bleeding in the postoperative setting is usually surgical in nature and, therefore, not correctable by platelet transfusion. However, bypass-induced platelet dysfunction may contribute to bleeding after cardiac surgery²⁸²; platelet transfusion may improve hemostasis in such situations.

Platelet transfusion is most useful in thrombocytopenic patients with microvascular bleeding (e.g., oozing or mucous membrane or gastrointestinal bleeding). Transfusion to achieve a platelet count of $50 \times 10^9/L$ is generally recommended^{250,258,262,279} for bleeding patients. However, hemostasis may be achieved through repeated platelet transfusion even in the absence of a demonstrable rise in platelet count. Transfusion is indicated in bleeding patients with platelet dysfunction, regardless of the platelet count.

Dilutional thrombocytopenia may occur after massive transfusion of red cells and plasma volume expanders. In the absence of platelet consumption, a platelet count of $<50 \times 10^9/L$ is not generally seen unless more than two blood volumes (20 red cell units in an adult) have been replaced.^{217,283,284} However, in settings such as trauma where there is activation of coagulation and consumption of platelets in addition to blood loss, there is some evidence that pre-emptive use of platelets in the resuscitation support may be of benefit.^{212,219,220}

In all situations, the clinical decision regarding platelet transfusions requires consideration of several variables, including an estimation of platelet count and function, cause of thrombocytopenia, and state of the coagulation system; the presence or likelihood of bleeding (the development of petechiae, spontaneous mucous membrane oozing, and retinal hemorrhages are often danger signals indicating hemostatic incompetence); and the hazards of transfusion, which include all those encountered with the transfusion of any blood product.

Platelet Refractoriness and Alloimmunization

Refractoriness to platelet transfusions is a clinical state that can be defined as an unacceptable recovery of transfused platelets on two or more occasions. As noted previously, a CCI of <5 to $7.5 \times 10^9/L$ measured at 10 minutes to 1 hour after the transfusion is a commonly used definition of an unacceptable response or, as a general rule of thumb, an absolute increment of $<13 \times 10^9/L$ after transfusion of six units of platelets to a 70-kg adult. Clinical factors reported to be associated with refractoriness to platelet transfusion are listed in Table 21.6.^{93,254,263,285,286} and ²⁸⁷

Amphotericin

Immune Causes of Refractoriness

The major immune cause of refractoriness is the presence of anti-HLA antibodies. These antibodies are stimulated by pregnancy or by transfusion of WBC-containing blood products. Platelets bear HLA class I antigens on their surface. Anti-HLA antibodies are produced by 30% to 50% of recipients of WBC-containing blood products (Table 21.7).¹²⁴ They are found in up to 30% of untransfused

P.568

women with a history of pregnancy.^{288,289} After exposure to blood products, up to two thirds of women with a history of pregnancy produce HLA antibodies.²⁹⁰ Transfusion of platelets that are serologically incompatible with a pre-existing HLA antibody typically results in no increase in platelet counts.^{291,292}

TABLE 21.7 EFFICACY OF LEUKOCYTE-REDUCED PRODUCTS IN PREVENTING TRANSFUSION-INDUCED HLA ALLOIMMUNIZATION

Note: This is a summary of prospective controlled trials in hematology and oncology patients. Each numerator indicates the number of patients developing HLA antibodies; the denominator indicates the number of patients transfused with that type of blood product. The number in parentheses represents the calculated proportion of patients making antibodies. Modified from Dzik WH. Leukoreduced blood components: laboratory and clinical aspects. In: Simon TL, Dzik WH, Snyder EL, et al., eds. Rossi's

principles of transfusion medicine, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2002:270-287.

The incidence of clinically significant alloantibodies to platelet-specific glycoproteins in transfusion recipients is unclear. Antibodies to platelet glycoproteins have been detected almost exclusively in patients who also have broadly reactive anti-HLA antibodies. Using the sensitive MAIPA (monoclonal antibody immobilization of platelet antigen) assays, investigators have reported detection of antibodies to platelet glycoproteins in as many as 25% of HLA-alloimmunized transfusion recipients.^{293,294,295} and²⁹⁶ A significant proportion of the antibodies detected have ill-defined specificity, and the contribution of such antibodies to platelet refractoriness is unclear. The presence of platelet-specific antibodies in patients who are broadly sensitized to HLA presents an enormous transfusion support challenge. Although many blood centers maintain HLA-typed donor registries, at present, very few of these donors are typed for platelet antigens. The solid-phase red cell adherence or recently developed MAIPA-based platelet crossmatching assays could theoretically be used to test HLA-selected products for compatibility with a patient's antiplatelet antibodies, although it has not yet been established whether these assays have adequate sensitivity and specificity for this application.

As discussed earlier, high-titered ABO antibodies have been implicated in platelet refractoriness. Many investigators recommend a trial of ABO-compatible products in refractory patients, although studies have not demonstrated a high likelihood of improvement.

Antiplatelet autoantibodies are usually associated with absolute refractoriness to platelet transfusion. However, in the event of life-threatening bleeding, patients with ITP may benefit clinically from repeated infusions of platelets even in the absence of a demonstrable rise in platelet count. Antifibrinolytics or recombinant factor VIIa may also be helpful in this setting, as discussed later (see "Role of Pharmacologic Agents in Managing Thrombocytopenic Patients").

Nonimmune Causes of Refractoriness

Of the nonimmune factors implicated in refractoriness, splenomegaly is the most potent. Transfused platelets pool in the enlarged spleen; increasing the dose of platelets does not necessarily improve the posttransfusion increment. Each of the other nonimmune factors listed in Table 21.6 has been reported to be associated with refractoriness, although the importance of each factor has not been demonstrated consistently.^{93,254,285,286,297}

Prevention of HLA Alloimmunization

Although platelets express HLA class I molecules on their surface, purified platelets do not appear to induce primary immunization to HLA antigens. It appears that the presence of WBCs is necessary, presumably because of their dual expression of both HLA class I and class II antigens.²⁹⁸ Multiple studies have demonstrated that the prophylactic use of leukoreduced blood products significantly decreases the incidence of HLA immunization in transfusion recipients (Table 21.7).^{124,299,300} Use of leukoreduced blood products is recommended for patients who are likely to require intensive platelet transfusion support, because the development of anti-HLA antibodies would complicate such support.

Purified platelets can stimulate a secondary immune response to HLA.²⁹⁸ Patients with prior pregnancy are highly likely to produce HLA antibodies after transfusion. HLA alloimmunization has been observed in up to two thirds of such patients. The use of leukoreduced products appears to be of limited benefit in such patients: HLA antibodies are produced by 33% to 44% of patients with a history of pregnancy despite the use of leukoreduced products.^{290,299,301}

As an alternative to removing WBCs from blood products, *in vitro* studies indicate that ultraviolet (UV) irradiation of WBCs abrogates their ability to present HLA antigens in mixed lymphocyte culture.^{302,303} *In vivo* studies demonstrate that UV irradiation of blood products is as effective as leukocyte reduction in preventing primary HLA alloimmunization.²⁹⁰ UV irradiation of platelet products requires special blood containers and equipment and is not currently available in the United States.

Early studies suggested that HLA alloimmunization in platelet transfusion recipients could be reduced by minimizing donor exposure through the use of pheresis platelets rather than pooled platelet concentrates.^{304,305} However, it has been shown that if all products are leukoreduced, there is no incremental benefit to the use of pheresis products.²⁹⁰

Diagnosis and Management of Alloimmunization

Historically, anti-HLA antibodies have been detected by lymphocytotoxicity assays. Newer methods of testing for HLA antibodies include enzyme or flow-based immunoassays in which HLA glycoproteins are immobilized on a plastic plate or beads.³⁰⁶ A commercially available solid-phase red cell adherence assay permits screening for serologic reactivity against platelets selected from inventory.³⁰⁷

Early studies demonstrated that thrombocytopenic patients with lymphocytotoxic antibodies could be successfully supported with platelets obtained from donors who were HLA-identical to the patient, or donors who were partially HLA-matched and whose lymphocytes were serologically compatible with the patient's antibody.^{291,308} These observations led to the practice of providing apheresis platelets from "HLA-matched" donors for patients with lymphocytotoxic antibodies. Depending on the availability of family members, the rarity of the patient's HLA type, and the size of the HLA-typed donor registry, it may be difficult or impossible to locate platelet donors who are HLA-identical to the patient.

Therefore, many platelets provided as HLA-matched bear one or more antigens that are foreign to the recipient. Serologic crossmatching of partially mismatched products can be used to identify those that are more likely to result in a good posttransfusion increment.^{291,292,309}

In most HLA-alloimmunized patients, the specificity of the antibody can be defined.^{297,310,311} Patients can be successfully supported with products that lack the HLA antigen(s) to which the antibodies are directed.^{297,310} If the platelet inventory is HLA-typed, products lacking the offending antigen(s) can usually be found in inventory; thus, many patients can be supported with products on the shelf, without the need for special donor recruitment or serologic crossmatching.

Alternatively, serologic crossmatching of HLA-untyped products may be used to support patients whose antibodies are not broadly reactive. For many alloimmunized patients, it is possible to identify serologically compatible platelets among HLA-untyped products in the blood center inventory using the solid-phase red cell adherence crossmatching assay.³⁰⁷ However, compatible products are unlikely to be found in inventory for patients who have broadly reactive antibodies; such patients require specific recruitment of HLA-selected donors.

In summary, HLA-alloimmunized patients may be supported (a) by using products from donors who are HLA-identical to the patient or who lack HLA antigens foreign to the recipient; (b) by using products that are partially HLA-matched and serologically compatible; (c) by identifying the specificity of the patient's HLA antibody and avoiding products that bear the offending antigen(s); or (d) by serologic crossmatching of products in inventory. These methods are equally effective clinically.²⁹⁷ The first method is often limited by the inadequate availability of donors. The last method is not applicable to patients with broadly reactive

P.569

antibodies, who comprise approximately 10% to 15% of alloimmunized patients.^{307,311}

It should be noted that HLA antibodies may appear or disappear over the course of a patient's treatment.^{93,297} It is important to monitor patients' responses to platelet transfusion and to reevaluate them serologically if they do not respond to products that were previously acceptable.

Platelet Transfusions for Refractory Patients

Strategies for the optimal use of platelets are undergoing evolution.²⁷⁸ A published guideline suggests withholding prophylactic transfusion for nonbleeding patients who do not achieve acceptable posttransfusion increments in platelet counts.²⁶¹ However, many clinicians arbitrarily transfuse one dose of platelets daily, based on the assumption that some platelets are necessary to maintain vascular integrity.²⁵⁵ For bleeding patients, many practitioners recommend infusion of larger or more frequent doses of platelets.^{254,312}

Role of Pharmacologic Agents in Managing Thrombocytopenic Patients

Attempts to improve responses with intravenous immunoglobulin (IgG) therapy in patients refractory to platelets have not convincingly demonstrated benefit; some found improved 1 hour but not 24 hour posttransfusion increments.³¹³ Fibrinolytic inhibitors were shown to be of value in avoiding platelet transfusions in aplastic patients,³¹⁴ by helping stabilize any clots that are being formed.³¹⁵ Anecdotal reports³¹⁶ have suggested that recombinant factor VIIa (rFVIIa) may stop bleeding, particularly in patients with refractory, severe thrombocytopenia.^{317,318} However, a randomized trial failed to demonstrate any difference between the placebo group and the three rFVIIa cohorts combined, in the primary endpoint of bleeding score at 38 hours³¹⁹. Raising red cell mass by blood transfusion or treatment with erythropoiesis stimulating agents (ESA) has been shown to improve coagulopathy related to anemia³²⁰ or uremia,³²¹ but evidence for clinical efficacy is needed. Thrombopoiesis-stimulating agents have been shown to be efficacious in improving platelet counts in patients with immune thrombocytopenias.^{322,323} Platelets contain significant amounts of micro RNAs that may provide proteins that affect hemostasis and inflammation.^{324,325} Finally, development of fibrinogen-coated, ADP-encapsulated liposomes may offer a promising platelet substitute.³²⁶

Selection of Platelet Products

ABO Group

The clinical importance of ABO compatibility in platelet transfusion is controversial. Platelets bear both intrinsic³²⁷ and adsorbed³²⁸ antigens of the ABH system. Transfusion of ABO-incompatible platelets may be associated with decreased posttransfusion platelet recovery and normal survival.^{329,330,331} and³³² The reduction in recovery is variable and may be related to the isohemagglutinin titer of the recipient. Rarely, a high titer of anti-A or anti-B may cause frank refractoriness to ABO-incompatible platelets.^{333,334} and³³⁵

Platelet products contain a significant amount of donor plasma. Rarely, high-titered donor isoagglutinins in platelet products may cause intravascular hemolysis of recipient red cells,³³⁶ especially platelets from group O donors.^{337,338} Some investigators have suggested that patients who receive platelets mismatched for ABO develop refractoriness at a higher rate than patients who receive ABO-compatible products.^{335,339,340} However, these studies were small, did not control for the presence of HLA antibodies, and differed in their observations as to whether it was cell or plasma compatibility that was important. Most important, patients who developed refractoriness to ABO-incompatible products did not show better responses when given ABO-identical products, suggesting that ABO may not have been the cause of refractoriness.^{338,340} In practice, it is difficult to ensure availability of ABO-identical platelet products, and many centers simply limit the volume of incompatible plasma transfused.

Rh Type

Platelets do not carry Rh antigens, and the donor's Rh type is important only because the red cells present in the platelet concentrate may immunize Rh-negative recipients. Although early studies found that as many as 19% of D-negative recipients of platelets from D-positive donors developed anti-D, several recent studies in hematology/oncology patients found that immunization did not occur.^{341,342} It is possible that the difference in observations is related both to an increase in intensity of chemotherapy as well as to a substantial improvement in the purity of platelet products. The red cell content of most apheresis platelets currently is below the dose thought to be immunizing. For most platelet recipients, anti-D prophylaxis would be of little benefit.³⁴³ For pediatric patients and females with future childbearing potential, however, it may be reasonable to consider administration of intravenous anti-D Ig to prevent D immunization.^{343,344} and³⁴⁵

PLASMA TRANSFUSION

Use of Plasma Components

FFP or FP24 are utilized in patients who are bleeding or who are having an invasive procedure and who are deficient in multiple coagulation factors or in a single factor for which there is no specific factor concentrate available. They are also used for replacement of clotting factors during massive transfusion, for reversal of warfarin (if immediate reversal is necessary), and as the replacement fluid for plasma exchange procedures in patients with TTP.^{3,346} They should not be used as volume expanders or for therapeutic plasma exchange for other disorders, because alternative fluids with lower risks of infectious diseases, allergic reactions, and TRALI are available for these purposes (e.g., crystalloid, albumin, starch). The typical dose of plasma is 10 to 20 ml/kg.³ Patients may not tolerate infusion of larger volumes. The expected rise in coagulation factor activity is approximately 10% for each 10 cc/kg of plasma infused.³⁴⁷

Efficacy of Plasma Transfusions

In a recent evidence-based review, the Transfusion Practices Committee of the AABB recommended plasma therapy for only a few clinical indications, based on the available evidence in the literature (which was assessed to be of "weak quality"): trauma patients with substantial hemorrhage, patients undergoing complex cardiovascular surgery, and patients with intracranial hemorrhage requiring emergency reversal of warfarin-associated coagulopathy.³⁴⁸ Patients with mild prolongations of the INR (less than 1.7) are not at risk of bleeding and do not need plasma therapy for minor procedures,³⁴⁹ so that for the majority of clinical settings there is ample evidence that plasma transfusions are inappropriate. However, logistical/technical barriers that prevent effective and timely plasma therapy (possibly resulting in plasma therapies that are "too little, too late") have probably contributed to the paucity of evidence demonstrating any benefit for plasma therapy.¹⁷⁷

One of the largest prospective studies of plasma transfusions and their effect on INR and bleeding included both medical and surgical patients with pretransfusion INR of between 1.1 and 1.85.³⁵⁰ The authors reported that less than 1% of patients

P.570

had normalization of their INR and only 15% had at least 50% correction. The median dose of plasma was 2 units (only 5 to 7 ml/kg), and there was no correlation between plasma dose and change in INR. This study had many of the limitations common to other reports³⁵¹ in this clinical arena: lack of control groups, only modest prolongation in coagulation tests, poorly-defined clinical endpoints (e.g., change in hemoglobin or need for transfusion), and/or an inadequate dose of plasma therapy.

The paucity of evidence for the benefit of plasma transfusion therapy has been accompanied by growing evidence that risks of plasma have been underrecognized; in a prospective study, 6% of transfused patients developed transfusion-associated cardiac overload,³⁵² which is much higher than previously-reported rates in retrospective studies.^{353,354} Transfusion-related acute lung injury³⁵⁵ is a significant cause of morbidity/mortality from blood transfusions, whose incidence has declined subsequently with use of plasma from male donors or female donors who have no history of pregnancy.³⁵⁶

GRANULOCYTE TRANSFUSIONS

Severe bacterial and fungal infections in the setting of prolonged chemotherapy-associated neutropenia are common causes of morbidity and mortality in the treatment of malignancy. Risk of serious bacterial infection appears as the neutrophil count falls below $1.0 \times 10^9/L$ and increases rapidly below $0.5 \times 10^9/L$. Fungal infections occur with much higher frequency as the neutrophil count falls below $0.2 \times 10^9/L$.³⁵⁷ Other risk factors include the duration of neutropenia and the rate of fall of the neutrophil count.³⁵⁸ The use of growth factors (e.g., granulocyte colony-stimulating factor [G-CSF]) has reduced the severity and duration of neutropenia, but many patients still have long periods of poor granulocyte production, lasting 2 to 3 weeks or longer.^{359,360} and ³⁶¹ Although the idea of enhancing host defenses with granulocyte infusions dates back 60 years, difficulty obtaining adequate granulocyte yields as well as safety concerns stifled the initial interest generated after early clinical successes in the 1970s.^{362,363} Modern apheresis techniques, growth factors which increased yields, and positive results from clinical trials led to renewed interest in applying granulocyte therapy to a wider range of patients.^{364,365}

Clinical Indications and Efficacy

Currently, there is no definitive evidence from controlled trials to support or refute the use of granulocyte transfusion therapy in neutropenic patients.^{366,367,368} Currently a large randomized control trial is being undertaken in an attempt to clarify this situation; nonetheless, prior clinical granulocyte transfusion trials in the setting of neutropenia give insight into populations that may benefit from this therapy. A review of 32 papers³⁶⁹ revealed that most studies have been uncontrolled, involved small heterogeneous populations of patients, and had different treatment approaches. Approximately 62% of the 206 patients with bacterial sepsis were reported to have benefited from granulocyte transfusion; conversely, 71% of 63 patients with invasive fungal infection did not respond to the infusions. Seven controlled trials were completed between 1972 and 1982: Three showed a positive effect, two showed benefit in specific patient populations, and two demonstrated no benefit. Some studies were likely limited by the cytoapheresis techniques used and the low cell yields obtained, as most donors were pretreated with corticosteroids only. Further analysis confirmed the importance of higher neutrophil doses as well as leukocyte compatibility in the three positive trials. More recent trials^{370,371} provide additional evidence supporting the use of granulocyte transfusions in critically ill neutropenic patients with bacterial as well as candida sepsis. Based on this information, granulocyte therapy may warrant consideration in severely neutropenic patients with bacterial infections unresponsive to typical antimicrobial therapy.

The applicability of granulocyte infusions in the setting of invasive fungal infections remains unclear. No study has shown clear efficacy in patients with active aspergillosis, although often the neutrophil dose was not known or was suboptimal. Limited clinical and animal model data give some indication of usefulness in the setting of candidal and noninvasive fungal infections.^{370,372,373} As the overall data are limited, a brief trial of granulocyte infusions may be warranted in patients with self-limited neutropenia and documented fungal infection who are refractory to standard antifungal therapy.

The effect of the prophylactic use of granulocyte transfusions to diminish the risk of serious infections in severely neutropenic patients during therapy of hematologic malignancies and after bone marrow transplantation has been investigated in a number of controlled trials.^{365,374} Although prophylactic granulocyte transfusion may decrease the risk of septicemia, the increased incidence of adverse effects observed with this therapy may outweigh the beneficial effects.^{375,376,377,378,379,380} and ³⁸¹ Until there are more published randomized, controlled clinical trials, the use of prophylactic granulocyte transfusions should be carefully considered and viewed as experimental.

Granulocyte transfusions may also be indicated in infected patients with severe neutrophil dysfunction (e.g., chronic granulomatous disease and leukocyte adhesion deficiency) who are not responding to appropriate antimicrobial therapy.

Although controlled trials have not been performed, transfused granulocytes do migrate within recipients and appear to be of therapeutic benefit.^{382,383} and ³⁸⁴ Because of the adverse effects associated with the transfusion of granulocytes, they should be used judiciously in the patient with severe documented infections, as the infusions may result in alloimmunization of the recipient and render him or her unresponsive to granulocyte transfusion therapy at a later date.

Neonatal bacterial sepsis continues to be a major cause of morbidity and mortality. The neutrophil function in neonates is impaired, with diminished chemotaxis and abnormal adhesion properties. Infection may result in neutropenia and depletion of the neutrophil storage pool. Granulocytes have been used to treat neonatal sepsis with varying results.³⁶⁷ The efficacy of this approach has been evaluated in six controlled trials with four studies demonstrating a survival benefit. Overall, data analysis does not show clear benefit when other available therapies are considered.^{362,367} When compared with standard therapy of intravenous Ig, neonates with group B Streptococcus may experience increased survival after receiving granulocyte support.³⁸⁵ Although conflicting data exist, centers that experience a high mortality rate in septic infants with neutropenia and ongoing neutrophil storage pool depletion may consider a trial of granulocyte therapy. The recommended dose is 1×10^9 granulocytes/kg of body weight.³⁶⁵

Donor Preparation/Selection

High granulocyte yields were initially obtained using preparations from donors with chronic myelogenous leukemia.³⁸⁶ Subsequently, methods were developed to collect sufficient granulocytes from normal donors. Apheresis became the standard method for collecting granulocyte concentrates.^{358,387,388} The quantity and quality of granulocytes obtained depend on the apheresis collection technique as well as the level of donor neutrophils. Infusion of hydroxyethyl starch or dextran to improve the sedimentation of donor red cells during centrifugation improves the efficiency of apheresis, but the granulocyte yield remains low³⁵⁸. Data suggested a daily granulocyte dose of about 10×10^{10} cells would be needed to achieve benefit.³⁸⁹ Oral corticosteroids produce a transient donor neutrophilia, but the collection yield remains in

P.571

the range of 2 to 3×10^{10} .³⁹⁰ Studies have shown the ability of G-CSF to increase the dose/collection. Donors treated with G-CSF with or without corticosteroids produce yields ranging from 2.4 to 9.9×10^{10} granulocytes. Although adverse effects occur in 30% to 69% of donors, most consist of mild to moderate degrees of bone pain, headache, myalgias, and fatigue. Data from the bone marrow transplant literature support the short-term safety of G-CSF use in healthy donors, although rare serious adverse events have been reported. Long-term follow-up data are limited and deserve further attention.³⁹¹ G-CSF administration to healthy donors is generally performed under institutional review board-reviewed protocols. Based on available evidence, donor pretreatment with a single dose of G-CSF (300 to 600 μ g subcutaneously) with dexamethasone (8 mg orally) 12 hours before collection gives reliable yields in a well-tolerated and cost-effective manner. Although repeated daily G-CSF stimulation and granulocyte collection have been reported,^{392,393} standard practice is to perform a second collection no sooner than 7 days after the initial cytapheresis procedure.³⁹⁴

Prospective granulocyte donors should meet all FDA and AABB standards for donation. Because granulocyte products must usually be transfused before completion of donor infectious disease testing, donors who have been tested recently are strongly preferred. Donors should also be free of disorders that might be exacerbated by dexamethasone (e.g., diabetes) or G-CSF (e.g., arthritis, vasculitis, splenomegaly, gout, thrombocytopenia). Donor/recipient pairs should be ABO-compatible because of the large RBC content in the product. RBC compatibility must be verified for each granulocyte product. CMV infections are a significant risk when seropositive donors are used for immunocompromised seronegative patients; therefore, CMV-negative patients should receive CMV-negative products.³⁸⁶

Patients requiring granulocyte transfusions may have become alloimmunized to HLA, and or RBC antigens during the course of prior transfusion support or pregnancy. Studies suggest decreased recovery and survival as well as failure of granulocytes to localize at the site of inflammation in patients who have lymphocytotoxic or granulocyte-specific antibodies.^{386,395} Recipients can be screened for the presence of HLA antibodies particularly if clinical suspicion for alloimmunization is high. In alloimmunized patients, HLA-compatible random donors or family members can be used; random donors may be preferred over family members if related allogeneic transplantation is anticipated as part of the treatment for the underlying disease. If laboratory tests for alloimmunization are not readily available, the likelihood of sensitization may be estimated by reviewing the patient's record for a history of platelet refractoriness or febrile transfusion reactions.

Granulocyte Collection/Storage

Once an appropriate donor has been selected and prepared, granulocytes are typically collected by leukapheresis during which 7 to 10 L of blood is processed over 3 to 4 hours. Hydroxyethyl starch is often used to reduce RBC contamination by

sedimentation. According to AABB standards, at least 1×10^{10} granulocytes/apheresis are collected.⁵ Current techniques achieve mean yields of 2 to 3×10^{10} /leukapheresis in 200 to 400 ml of plasma, with 10 to 30 ml of RBCs, and 1 to 6×10^{11} platelets. For pediatric recipients, whole blood buffy coats from donors stimulated with G-CSF may present an alternative to apheresis.³⁹⁶ Although granulocytes can be stored for up to 24 hours at room temperature, transfusion within 8 hours of collection is recommended. Biochemical assessments of the effects of storage on subsequent function (e.g., nicotinamide adenine dinucleotide phosphate oxidase activity, adhesion protein expression, respiratory burst activity, and bactericidal activity) reveal that effective storage may be possible for up to 48 hours at 10°C.³⁹⁷

Administration of Granulocytes

Granulocytes should be administered on a daily basis until the patient's endogenous neutrophil count rises to 0.5×10^9 /L or until the infection clears. Granulocyte concentrates should be given through a standard filter set to ensure that aggregates are not administered. The concentrate should be given slowly (over 1 to 2 hours) with the patient under constant observation, including the use of pulse oximetry. Transfusion reactions occur in 10% to 50% of patients but are usually mild, consisting of fever and chills. Premedication with antihistamines, acetaminophen, or steroids is common practice before infusion. More severe reactions occur in 1% to 5% of patients and tend to be pulmonary in nature. A serious potential interaction between granulocyte transfusions and amphotericin B has been reported,³⁹⁸ but this association has not been substantiated by others.^{399,400} Nevertheless, many physicians administer granulocytes and amphotericin at least 8 hours apart to limit the potential for increased pulmonary toxicity. If there are any signs or symptoms of respiratory distress, the transfusion should be discontinued immediately, the recipient should be examined for hypoxemia or pulmonary edema, and a chest radiograph should be done to assess for pulmonary infiltrates. If major adverse effects do occur, the recipient should be studied for the presence of antibodies that react with neutrophils. Granulocyte products contain lymphocytes and are capable of causing transfusion-associated GVHD (TA-GVHD). Thus all granulocyte products should be irradiated with 1500 to 3000 cGy to prevent transfusion-related GVHD without significantly impairing granulocyte function.³⁹⁷ Pre- and posttransfusion neutrophil counts should be determined to guide therapy. With large doses ($>8 \times 10^{10}$), neutrophil increments may exceed 2×10^9 /L immediately after infusion and may last for 24 to 48 hours.⁴⁰¹

ADVERSE EFFECTS OF BLOOD TRANSFUSION

The potential complications of blood transfusion therapy are many, but most present problems only in patients requiring repeated or large numbers of transfusions. The risks associated with the transfusion of any specific unit of blood are low. However, the risks must be weighed against the benefits at the time each transfusion is ordered.

Transfusion complications can be classified as immunologic and nonimmunologic (Table 21.8). Many of the immune reactions are caused by the stimulation of antibody production by foreign alloantigens present on transfused red cells, leukocytes, platelets, or plasma proteins. Such alloimmunization may lead to immunologically mediated reactions when transfusions carrying these antigens are administered in the future. These include hemolytic reactions caused by red cell incompatibility; febrile or pulmonary reactions caused by leukocytes and platelet antigens; allergic or anaphylactic reactions caused by antibodies reacting with soluble antigens, usually plasma proteins, in the transfused material; and GVHD caused by engraftment of transfused lymphocytes in immunosuppressed recipients.

The nonimmune reactions are caused by the physical or chemical properties of the transfused blood products, as well as contaminating infectious agents. Nonimmune reactions include circulatory overload and certain adverse effects encountered specifically when large numbers of transfusions are given.

Immunologic Transfusion Reactions

Alloimmunization to Transfused Antigens

Alloantibodies Reacting with Red Cell Antigens

Although the antigenic composition of transfused red cells always differs from that of the recipient, only a minority of

P.572

multitransfused recipients develop red cell alloantibodies. The risk of red cell alloimmunization has been estimated at 1.0% to 1.4% per unit transfused^{402,403}; in multitransfused patients, the incidence of such antibodies ranges from 5% to 30%.^{404,405} Multiple red cell antibodies may be encountered. Antibodies to Rh system antigens and to Kell (K) are most often detected. Antibodies to antigens of the Duffy (Fy) and Kidd (Jk) systems also occur, but transfusion-induced antibodies to other red cell antigens are less commonly found.

West Nile virus

Parasites: malaria, *Babesia*, trypanosomes

Variant Creutzfeldt-Jakob disease

Bacterial contamination

Other organisms

The production of such antibodies is a property of both the recipient's immune response and the immunogenicity of the different red cell antigens. The incidence of antibodies does not appear to be related to the patient's diagnosis. For example, patients with hemoglobinopathies, thalassemia, and leukemia and those undergoing surgery requiring multiple transfusions produce antibodies with approximately the same frequency.^{404,406} The reported incidence of RBC alloimmunization for patients with thalassemias is 5% to 10%, versus 20% to 30% for those with sickle cell anemia. The increased incidence of alloimmunization in sickle cell patients has been attributed to the difference in race between the blood donor pool and the patient population.⁴⁰⁷ As a result, there is a greater likelihood of minor-antigen incompatibility between donor and recipient. The differing immunogenicity of various red cell antigens also plays a role. For patients with sickle cell anemia, red cells phenotypically matched for Rh and Kell antigens are recommended. This measure was shown to reduce the alloimmunization rate in this population from 3% to 0.3% per unit transfused.⁴⁰⁸

Alloantibodies Reacting with Leukocyte Antigens

Alloimmunization to HLA and other leukocyte-associated antigens has been discussed earlier with respect to problems encountered in granulocyte and platelet transfusion. These antibodies occur mainly in multiparous women^{289,409} and multitransfused patients. In patients receiving nonleukoreduced transfusion support for aplastic anemia or acute leukemia, 20% to 70% become immunized to HLA antigens.⁴¹⁰ Interestingly, HLA alloimmunization is significantly increased in male patients with pre-existing RBC antibodies compared to multiply transfused male patients without such antibodies.⁴¹¹ As discussed in the section "Platelet Transfusion" and shown in Table 21.7, the prophylactic use of leukocyte-reduced blood products significantly reduces the incidence of HLA alloimmunization in patients with no prior exposure to these antigens.

Alloantibodies Reacting with Plasma Proteins

Although antibodies to soluble plasma proteins such as lipoproteins and to Gm and Inv determinants on IgG are often detectable in multitransfused patients, transfusion reactions have rarely been attributed to such antibodies.^{412,413} and ⁴¹⁴ Some anaphylactic reactions are attributed to anti-IgA antibodies,^{415,416,417} especially in patients who are IgA-deficient, although the presence of antibodies that react with IgA is not always clearly correlated with the occurrence of this type of transfusion reaction.⁴¹⁸

Hemolytic Transfusion Reactions

The development of antibodies capable of reacting with red cell antigens may lead to red cell destruction, usually involving transfused rather than recipient cells. The clinical significance of such reactions ranges from life-threatening to trivial. Whether hemolysis occurs immediately within the circulation, more slowly within the reticuloendothelial system, or not at all depends on the antigen and antibody involved.^{419,420} and ^{421,422}

The incidence of such reactions is variably reported. Several studies from the Mayo Clinic document a hemolytic reaction rate, both immediate and delayed, of between 1 in 6,200 and 1 in 1,400 red cell transfusions. In these reports, reactions caused by clerical error and ABO mismatching were virtually nonexistent, but some reactions were attributed to weak atypical antibodies missed in pretransfusion testing.^{419,423} The high reaction rate was related in part to a high index of suspicion and in part to the use of sensitive tests for serologic evidence of minor delayed hemolytic transfusion reactions (DHTRs). In contrast, in a review of fatal hemolytic reactions reported to the US Bureau of Biologics (now the FDA's Center for Biologics Evaluation and Research or CBER), 86% were caused by ABO incompatibility, and of these, 89% were caused by simple clerical error.^{424,425} More recent FDA data has shown a decrease in deaths due to ABO incompatibility although overall, hemolytic transfusion reactions still represent a leading cause of transfusion-related mortality.⁴²⁶

Immediate (Intravascular) Hemolytic Transfusion Reactions

Immediate hemolytic transfusion reactions (IHTRs) are most typically associated with ABO incompatibility, because anti-A and anti-B antibodies are predominantly IgM and are capable of binding complement and causing immediate destruction of red cells.

P.573

An IHTR caused by ABO incompatibility is rare and is usually related to human error. Other red cell antigens such as Jk^a, K, and Fy^a (which may bind complement) may also lead to such reactions.

Infrequently, hemolytic transfusion reactions may be caused by destruction of recipient red cells after the transfusion of plasmacontaining antibodies.^{427,428} For example, anti-A₁ occurring naturally in group A donors of subgroup A₂ has been reported to cause hemolytic transfusion reactions.⁴²⁹ More recently, hemolytic transfusion reactions have been reported

in association with apheresis platelets containing abnormally high titer ($>1:250$) anti-A or anti-B antibodies in the plasma. Plasma volume reduction is recommended for such products if the plasma is incompatible with the recipient.⁴³⁰ Hemolytic reactions caused by the transfusion of plasma containing other antibodies are extremely rare, as blood donors are screened for red cell antibodies other than ABO.

Signs and Symptoms. IHTRs occur soon after the incompatible transfusion has begun. Occasionally, they are mild; more typically, there is a sudden change clinically. Fever with or without chills is one of the most common manifestations of such reactions. Other signs and symptoms include anxiety, chest or back pain, flushing, dyspnea, tachycardia, and hypotension. If the patient is under general anesthesia, these symptoms may not be recognized; only severe hypotension and evidence of oozing or hemoglobinuria serve as clues to the presence of a hemolytic reaction.

IHTRs may be life-threatening, and complications may include acute renal failure, shock, and intravascular coagulation. It has been estimated that a fatal immediate hemolytic reaction occurs in approximately 1/600,000 red cell transfusions⁴²². The mortality of a severe IHTR increases with the amount of blood transfused, with a 44% mortality rate in patients receiving more than 1 L of incompatible blood.

Pathophysiology. The primary event in IHTRs is the interaction between the antibody and the red cell membrane, resulting in the development of immune complexes, activation of complement leading to the release of C3a and C5a with anaphylatoxic activity, and the coagulation mechanism via cytokines and factor XII (leading to both consumptive coagulopathy and generation of bradykinin). Vasomotor mediators implicated in the transfusion reaction include histamine, serotonin, and cytokines. Shock results from release of such vasoactive substances.^{421,422}

The renal failure that may occur in this setting is of complex and poorly understood etiology but appears to be primarily ischemic, caused by a combination of hypotension, vasoconstriction (via nitric oxide inactivation by hemoglobin), and intravascular coagulation. The free hemoglobin circulating in such patients was once thought to be the major cause of renal failure by precipitating in and obstructing the renal tubules, but there is adequate evidence to discount this hypothesis. Infusion of incompatible red cell stroma, free of hemoglobin, is sufficient to produce acute renal failure.⁴²⁰

Management. On any suspicion of a hemolytic transfusion reaction, the transfusion must be discontinued immediately, as the severity of the reaction is related to the volume of red cells infused. A recheck of the patient's identity with the information on the discontinued blood unit is necessary to rule out bedside identification errors. The reaction must be reported to the blood bank without delay; a posttransfusion blood sample and the discontinued bag of blood should be sent to the blood bank for investigation of the cause of the reaction. Hydration must be begun immediately to prevent renal failure. An infusion of normal saline is given to maintain the blood pressure and increase the urine flow rate to 100 ml/h. Diuretics may be needed to maintain urine output. If oliguric renal failure develops, fluid challenges must be restricted. Once renal failure is established, the usual supportive measures, including fluid restriction, management of electrolyte balance, and dialysis, are required.

Additional interventions may be needed depending on the severity of the reaction. Some recommend early heparinization at moderate dose as management of coagulopathy if no specific contraindication exists; its use remains controversial. The patient may require support of the defective hemostatic mechanisms with platelets and cryoprecipitate or plasma. In massive intravascular hemolytic transfusion reactions, exchange transfusion has been performed.⁴³¹

Investigation of Immediate Transfusion Reactions. The following steps must be carried out in the investigation of patients with immediate transfusion reactions. The patient's identity must be confirmed, and all the records on the patient and the donor blood label must be checked for clerical errors. A new, properly labeled sample of blood must be drawn from the patient and sent to the blood bank with the discontinued unit of blood. The posttransfusion sample must be visually checked for hemolysis. In intravascular reactions, free plasma hemoglobin can be detected most quickly by centrifuging a tube of blood anticoagulated with ethylenediaminetetraacetic acid (EDTA) or heparin; pink to red plasma indicates intravascular hemolysis—that is, evidence of red cell destruction. There must be an investigation for possible alloantibodies. A direct antiglobulin test must be performed on the specimen submitted at the time of the reaction. If the test is positive, the pretransfusion sample should also be tested, because the patient may have had a positive direct antiglobulin test before transfusion.

Red cell typing should be repeated on all specimens. If the posttransfusion ABO and Rh types do not agree with pretransfusion results, there has been an error in patient identification or typing. Antibody detection tests should be repeated on the pre- and post-reaction samples. The direct antiglobulin test on the post-reaction specimen may reveal sensitization of red cells in the patient only if the antibody or complement-coated transfused incompatible cells have not been immediately destroyed. A serologic crossmatch should be positive, although the antibody may not be readily demonstrable in serum at the time the reaction is suspected clinically. In a minority of patients in whom there is a high

clinical suspicion of a hemolytic transfusion reaction, no immunologic abnormality may be identified. In some, repeated examination for antibodies over a prolonged period of time may eventually reveal the cause; in others, results may be persistently negative. In such patients,⁵¹Cr red cell survival testing may be of value in documenting hemolysis caused by incompatibility.^{432,433,434} and ⁴³⁵

Patients with major hemolytic transfusion reactions should be assessed for the possible presence of intravascular coagulation, and their renal function should be monitored closely. Urinary hemosiderin or free hemoglobin in the urine may also be detected; wine-colored urine is typical of intravascular hemolysis. The laboratory can confirm the identity of the pigment. Demonstration of methemalbuminemia, reduced serum haptoglobin, or hyperbilirubinemia may provide supportive evidence.

Prevention. Most IHTRs are preventable. The most likely cause is human error, such as mislabeling of the patient sample, drawing the sample from the wrong patient, transcription errors, and improper identification of the unit with the recipient. Mechanisms to ensure positive identification of the patient (recipient), the blood sample, and the transfusion component must be in place to prevent IHTRs.⁵

Delayed Hemolytic Transfusion Reactions

DHTRs generally are much milder than those occurring immediately, and red cell destruction is predominantly extravascular.^{419,423,436,437} The transfused red cells are destroyed beginning 2 to 10 days after a transfusion. Investigation may reveal the presence of a red cell antibody not detected in the pretransfusion blood sample. The direct antiglobulin test is often positive, but the reaction is transient and may be missed if it is performed too late. The test reverts to negative as the incompatible red cells are removed from the circulation.

P.574

DHTRs almost always represent secondary, or anamnestic, antibody responses. On first exposure to an immunogenic red cell antigen, a primary antibody response generally is delayed in onset and slow to reach its peak. For example, anti-D appears a minimum of 4 to 8 weeks after transfusion and may not develop for up to 5 months, after most or all the donor red cells have been removed by the aging process.⁴¹⁹ The antibody level gradually declines, and antibody screening and crossmatch tests may be negative. After a subsequent transfusion, the previously sensitized recipient manifests a much more brisk immune response, with high concentrations of IgG antibody developing within days. Donor cells remaining in the circulation may become coated with antibody and removed by the reticuloendothelial system. Rarely, primary immunization after transfusion may lead to a DHTR.⁴³⁸

In delayed hemolytic reactions, destruction of the sensitized red cells is predominantly extravascular; that is, the IgG-coated red cells are removed by the reticuloendothelial system. Often, there are no symptoms, with a new red cell antibody and positive direct antiglobulin test detected incidentally.⁴³⁹ If present, symptoms and signs may include fever, falling hematocrit, jaundice, and, infrequently, hemoglobinemia and hemoglobinuria. Rarely, the reactions may be dramatic; renal failure is uncommon, but fatalities have been reported. The antibodies responsible for DHTRs are well defined. Antibodies to Kidd (Jk) antigens and to antigens of the Rh system are the major offenders, with anti-Kell and anti-Duffy (Fy) implicated in most other delayed reactions. Anti-Kidd antibodies are particularly troublesome because the plasma concentration of these antibodies declines more rapidly than others, so pretransfusion tests are more commonly negative in patients who are in fact sensitized.²³⁶

Investigation of Delayed Hemolytic Transfusion Reaction. If a DHTR is suspected, a fresh blood sample should be obtained from the patient. This sample should be screened for the presence of previously undetectable red cell antibodies. A direct antiglobulin test should be done. If it is positive, the antibodies should be eluted from the red cells and identified. If the transfused cells have already been destroyed, the direct antiglobulin test will not be positive, but an antibody should be detectable in the patient's serum. The physician must be advised and the patient given a card indicating the presence of the antibody. The blood bank must retain a permanent record of clinically significant antibodies because the antibody may again become undetectable.

Management. In most instances, no specific therapy is necessary. The few patients who experience severe reactions should be treated with adequate hydration. If further transfusions are indicated, crossmatch-compatible blood negative for the offending antigen(s) should be administered. The physician and patient should be informed about the antibody so that transfusions may be administered safely in the future.

Pseudo-hemolytic Transfusion Reactions

In patients manifesting a clinical syndrome consistent with intravascular hemolysis, but in whom no blood group incompatibility can be identified, other explanations should be considered. Conditions that mimic hemolytic transfusion reactions are called pseudo-hemolytic transfusion reactions.⁴²¹ These include bacterial contamination with organisms such as *Yersinia*, resorption of large hematomas, and hemolysis caused by drug reactions or vascular prostheses. Pretransfusion hemolysis of donor blood caused by mechanical trauma, freezing, heat, or hypotonic solutions, should always be considered a potential cause of such a reaction.⁴²¹

Febrile Nonhemolytic Transfusion Reactions

FNHTRs^{440,441,442} have been reported in a variable proportion of patients receiving transfusions, ranging between 0.5% and 3.0%; they are more common in multiply transfused patients. The typical reaction consists of a chill followed by fever of 1°C or greater, usually during or within a few hours of the transfusion. Headache, nausea, and vomiting may occur. Occasionally, the reaction may be severe but usually these reactions are mild. Whatever their degree, febrile transfusion reactions usually run their course within a few hours. Some causes of FNHTRs are as follows.

Alloimmunization to antigens on leukocytes and platelets is one of the most common causes of nonhemolytic febrile reactions. Early studies detected the presence of leukoagglutinins in such patients.^{443,444} HLA antibodies are most commonly found, followed by platelet-specific antibodies; granulocyte-specific antibodies are detected in only a minority of patients.^{445,446} and ⁴⁴⁷

Another cause of FNHTRs is the transfusion of cytokines that have developed during product storage, especially in nonleukoreduced whole blood-derived platelet concentrates stored at room temperature.⁴⁴⁸ During storage, leukocytes in platelet concentrates release cytokines that appear to be responsible for the febrile reaction.¹²⁶ The causative role of accumulated cytokines is supported by the observation that leukoreduction filtration after storage does not eliminate many of the FNHTRs to platelet concentrates.¹²⁷ The incidence of FNHTRs to nonleukoreduced platelet concentrates increases with the age of the platelet concentrate and the leukocyte concentration in the product. The reactions appear to be mediated by the supernatant of the platelet products.^{126,129,449} The concentration of cytokines in platelet concentrates and incidence of FNHTRs can be decreased by leukoreducing the products soon after collection. Apheresis platelets are leukoreduced by the collection technology and have reduced cytokine levels.⁴⁵⁰

The possibility of bacterial contamination of the product must be considered as a possible cause of FNHTR. Symptoms caused by transfusion of bacteria or their toxins can be mild or may be fatal. Platelet components are involved more often because they are stored at room temperature. However, certain organisms such as *Yersinia enterocolitica* proliferate in red cells at storage temperatures of 1°C to 6°C. Bacterial contamination is often not considered as a cause of a febrile reaction; it may be more prevalent than reported because of underinvestigation.^{451,452} and ⁴⁵³

Management of Febrile Reactions

The approach to management of febrile transfusion reactions must be based on an understanding of all the possible causes. Although many such reactions are caused by WBC alloimmunization or cytokines, fever may also be an indication of an unsuspected hemolytic transfusion reaction or contamination of the donor blood by bacteria or endotoxin. For these reasons, every transfusion complicated by a febrile transfusion reaction should be discontinued until the patient has been carefully assessed by a physician and the blood bank alerted. Although controversial, the physician, depending on the clinical condition of the patient and the institution's policies regarding such steps, may elect to restart the transfusion if a hemolytic or bacterially contaminated transfusion has been ruled out.

The possibility of a hemolytic reaction should be considered when fever occurs. If suspected, the donor unit, along with a patient blood specimen, should be returned to the blood bank for investigation. Other tests for hemolysis should be done as discussed previously, if clinically indicated. The donor unit and patient blood should be cultured if there is any suspicion of bacterial contamination.

The symptoms of a febrile transfusion reaction may often be ameliorated with an antipyretic such as acetaminophen or hydrocortisone in patients who develop severe reactions. Meperidine may be used to decrease or stop severe shaking chills. Antihistamines are indicated only if the patient also has allergic symptoms such as hives.

Prevention of Febrile Transfusion Reactions

Febrile transfusion reactions to red cells occur most commonly in patients who have been sensitized to WBC antigens by previous

transfusions or pregnancies. In such patients, the risk of a febrile transfusion reaction varies with the leukocyte content of the donor unit. Use of leukoreduced red cells may decrease the incidence of FNHTRs.^{454,455} and ⁴⁵⁶ Every patient who experiences a reaction does not routinely need specific preventive measures, because only a minority will have a second reaction.

When whole blood-derived platelets are given, febrile reactions are common. Removal of leukocytes from these components at the time of transfusion often fails to prevent FNHTR because of the high level of cytokines in these products.^{126,129} Reduction of the level of cytokines by using platelet concentrates stored for a shorter time, prestorage leukoreduction of the platelet concentrates, plasma reduction, or use of apheresis platelets reduces the incidence of FNHTR to platelet products.^{79,457} If reactions persist, premedication with antipyretics or corticosteroids may be required. Because granulocyte concentrates cannot be modified by leukoreduction, premedication should be considered in patients who receive these products.

Transfusion-related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) most commonly presents as severe respiratory distress of sudden onset, caused by a syndrome of noncardiogenic pulmonary edema resembling the adult respiratory distress syndrome.^{458,459} Chills, fever, chest pain, hypotension, and cyanosis, as well as the usual manifestations of pulmonary edema, may be seen. TRALI is reported by the FDA as the number-one cause of transfusion-associated fatality.^{426,460} The incidence of TRALI varies greatly, from 1 in 5,000 to 1 in 557,000 depending on the blood component involved.^{355,426}

It is hypothesized that TRALI reactions may be the result of two cumulative events⁴⁶¹: the first event is linked to the patient (i.e., underlying sepsis, hematologic disease, and/or postsurgical status), and the second event is related to the transfusion of potential granulocyte primers such as inflammatory cytokines, active lipids, and/or alloantibodies.^{355,462} The diagnosis of a TRALI reaction is based on the onset of acute lung injury (ALI) within 6 hours of transfusion.^{463,464} ALI is characterized by an acute onset of hypoxemia (oxygen saturation <90% by pulse oximetry for a patient breathing room air or a $\text{PaO}_2/\text{FiO}_2 \leq 300$ mmHg), bilateral infiltrates on frontal chest radiograph, and no evidence of circulatory overload. Based on studies of adult respiratory distress syndrome, which has similar pulmonary manifestations, it has been suggested that agglutination of granulocytes and complement activation occur in the pulmonary vascular bed, leading to capillary endothelial damage with consequent fluid leak into the alveoli.⁴⁶⁵

Management involves supportive measures for the pulmonary edema and hypoxia, including ventilatory support if required. Hemodynamic monitoring may be required to determine whether fluid overload is a factor; if not, diuretics are of no proven value.⁴⁶⁶ The AABB requires evaluation of donors implicated in TRALI.⁵ Donors whose plasma is implicated in such reactions should be examined for the presence of granulocyte-specific and HLA antibodies that react with recipient leukocytes. It is recommended to avoid further transfusion of plasma-containing products from implicated donors found to have anti-HLA or antigranulocyte antibodies. In 2006, the AABB recommended that blood banks minimize the production of high-plasma-content components (such as plasma products and pheresis platelets) from donors at risk for alloimmunization (e.g., women with a history of pregnancy).¹⁸ This change has resulted in a decrease of reported TRALI cases^{355,356,426}.

Allergic Reactions

Allergic reactions are common in transfusion recipients, with an estimated incidence of 1% to 3%,⁴⁴¹ but their actual incidence may be higher because they are often not reported. They range from urticarial lesions (hives), other skin rashes, bronchospasm, and angioedema to anaphylactic shock. Minor reactions are doserelated, with an incidence related to the volume of plasma transfused. Whole blood and plasma are more likely than concentrated red cells to cause such reactions; washed red cells or albumin are rarely implicated. Minor urticarial reactions are the only transfusion reactions that do not necessitate immediate discontinuation of the transfusion. Fortunately, the incidence of severe anaphylactic transfusion reactions is very low, as such reactions can be life-threatening.

Most allergic reactions are thought to be mediated by recipient IgE to proteins or other soluble substances in donor plasma. The interaction between the antigen and IgE stimulates the release of histamine from mast cells and basophils. Most patients do not have repeated allergic reactions, but those with a history of atopy are at higher risk for additional reactions. For patients with repeated allergic reactions, premedication with an H₁-blocking antihistamine is usually sufficient for prevention. If maximal premedication fails to control the allergic response, reducing the plasma content of the transfused blood product is another option. This can be accomplished by centrifuging the product and removing almost all the plasma or by red cell washing.

In patients with severe anaphylactoid or anaphylactic reactions, antibodies reacting with IgA in donor plasma should be considered. The incidence of genetically determined IgA deficiency in the otherwise normal population is high, ranging from 1 in 400 to 1 in 500.⁴⁶⁷ Without necessarily having prior transfusion exposure, approximately 20% to 25% of such patients produce antibodies to IgA, generally class-specific (i.e., reacting with all IgA molecules). Such patients should be transfused, when necessary, with washed red cells⁴⁶⁸ or with IgA-deficient blood products. In addition, many patients with normal IgA levels have antibodies that react with some, but not all, IgA molecules; the incidence of such limited-specificity antibodies has been reported at 2% of normal adults,⁴⁶⁹ but the incidence may be as high as 21% in multiply transfused patients.⁴⁴⁰ The concentration of such limited-specificity antibodies generally is low, and the resulting reactions are usually milder, but the possibility of a major reaction exists.⁴¹⁷

Posttransfusion Purpura

Posttransfusion purpura^{470,471} and ^{472,473} is the development of life-threatening thrombocytopenia 5 to 10 days after transfusion. This rare complication is caused by the development of alloantibodies directed against platelet-specific antigens; anti-HPA-1a is often implicated, although antibodies with other specificities have also been reported (see Chapter 47). Posttransfusion purpura is thought to occur as a result of a secondary immunologic response to the platelet-specific antigen, most patients having been sensitized by prior pregnancy or transfusion. The mechanism of destruction of the patient's own platelets is uncertain. Management includes high-dose IVIG,⁴⁷⁴ corticosteroids,⁴⁷⁵ or plasma exchange.⁴⁷³

Posttransfusion thrombocytopenia may also be associated with the passive administration of a platelet-specific antibody.^{476,477} and ⁴⁷⁸ Both anti-HPA-1a and anti-HPA-5a have been implicated; these cases can be defined as passive posttransfusion purpura, and the resulting thrombocytopenia occurs within hours of the transfusion. It is important to identify the donors of these blood products to prevent further infusion of plasma-containing products from such donors.

Transfusion-related Immunomodulation

Allogeneic blood transfusion results in the transfer of not only RBCs, but also significant amounts of potential immune effector cells, their products (e.g., cytokines), and various substances that may be seen by the host immune system as foreign antigens.

P.576

A large body of literature exists that substantiates the modulation of host immune systems by transfused allogeneic cells and substances, raising the possibility of the development of clinical syndromes generally referred to as transfusion-related immunomodulation (TRIM).⁴⁷⁹ Beneficial transfusion-related immunomodulatory effects have been reported in renal transplant patients, women with recurrent spontaneous abortions, and patients with Crohn's disease.⁴⁸⁰

A large number of clinical studies have been performed specifically addressing two potential harmful TRIM-associated effects: cancer recurrence and postoperative bacterial infections. The aim of the studies has been to document TRIM and to ascertain the potential benefit of leukoreduction or use of autologous blood.^{481,482,483,484,485,486,487,488} and ⁴⁸⁹ Despite some reported observations of a transfusion-associated increased risk of cancer recurrence or postoperative infections, many studies include potential confounders or sources of bias. Meta-analyses have concluded that a deleterious clinical effect of transfusion immunomodulation remains controversial.^{490,491,492}

Transfusion-associated Graft-versus-Host Disease

Most cellular blood products, including red cell, platelet, and granulocyte products, contain viable, immunocompetent T lymphocytes.⁴⁹³ When transfused into immunoincompetent recipients, these donor lymphocytes may proliferate in the patient and lead to the clinical syndrome of transfusion-associated graft-versus-host disease.^{494,495} TA-GVHD has also been reported in immunocompetent patients, especially those who receive transfusions from family members or from random donors who share HLA antigens, as is the case when the donor is homozygous for a shared HLA haplotype.^{496,497} In these cases, the recipient does not recognize the donor cells as foreign, allowing the transfused lymphocytes to proliferate and cause TA-GVHD. A higher incidence has been reported in countries such as Japan, whose populations are genetically similar.

Transfusion of leukocyte or platelet concentrates or fresh blood has been responsible for most cases of posttransfusion GVHD. Frozen-thawed plasma products (FFP, cryoprecipitate) have not been definitively associated with TA-GVHD. TA-GVHD occurs earlier than that seen after bone marrow transplantation, usually within 1 to 2 weeks, but is otherwise similar.⁴⁹⁸ Fever is the most common symptom, followed by a typical erythematous, maculopapular skin rash that begins centrally and spreads peripherally to the hands and feet. Abnormalities of hepatic function, nausea, and bloody diarrhea

often occur as the process progresses. Leukopenia followed by pancytopenia due to marrow failure is quite common in TA-GVHD and is seen most often 2 to 3 weeks after the onset of symptoms. The diagnosis is based on the clinical picture and can be confirmed histologically with a skin biopsy. Laboratory confirmation that the GVHD is transfusion-induced can be obtained by demonstrating the presence of donor lymphocytes in the patient. This can be done by HLA typing of patient and donor cells by DNA methods for class I and II antigens, by cytogenetic analysis, or by analysis of DNA microsatellite polymorphisms or variable-number tandem repeats.⁴⁹³ Severe systemic infections are the most common cause of death, which often occurs within 3 to 4 weeks from the time of the implicated transfusion. Despite aggressive treatment, the fatality rate in TA-GVHD is significantly higher than that associated with bone marrow transplantation and has been reported to be >90%.⁴⁹⁸

Corticosteroids, antithymocyte globulin, cyclosporine, and growth factors have all been used with minimal success in the treatment of TA-GVHD. Although a few reports of spontaneous resolution have been reported, current treatment approaches have used combinations of immunosuppressant medications with lymphocyte-directed antibody therapy (anti-CD3, anti-interleukin-2 receptor, antithymocyte globulin). Because of the lack of effective treatment regimens, TA-GVHD should be prevented by pretransfusion irradiation of all blood products administered to patients at risk. Irradiation inhibits proliferation of donor lymphocytes with little significant adverse effect on red cell, platelet, or granulocyte function. Changes in the red cell membrane do occur that result in an increased loss of potassium from the cell, limiting the storage time of irradiated red cells to 28 days. This may be important in neonates, as the dose of free potassium may be high in a relatively large-volume transfusion, necessitating the use of freshly irradiated or washed RBCs. The recommended dose for the irradiation of blood and blood products is 2,500 cGy at the center of the irradiation field, with a minimum dose of 1,500 cGy at any point in the field.^{5,131}

Based primarily on case reports and reviews, a number of immunosuppressed and immunocompetent patient groups can be stratified according to risk for developing TA-GVHD⁴⁹⁸ (Table 21.9).

Nonimmunologic Adverse Effects of Blood Transfusion

Transfusion-associated Circulatory Overload

Transfusion of red cell preparations or plasma products may result in transfusion-associated circulatory overload (TACO). In chronically anemic patients, the plasma volume expands so that the blood volume is normal. Virtually the entire volume of the blood product infused remains in the circulation; in elderly patients with limited cardiac reserve or in severely anemic patients in congestive heart failure, transfusion may lead to fatal pulmonary edema. Diuretic therapy and other measures to manage heart failure may be of some benefit; partial exchange transfusion may be indicated. Prevention of these reactions is most important. Transfusions should be administered slowly, at a rate of 1 to 2 ml of blood/kg of body weight per hour, with the

P.577

patient under close observation. Splitting red cell components or volume-reducing apheresis platelets can be helpful in managing the most difficult cases.

TABLE 21.9 PATIENTS AT INCREASED RISK FOR TRANSFUSION-ASSOCIATED GRAFT-VERSUS-HOST DISEASE

High Risk

Bone marrow transplant (allogeneic and autologous)

Intrauterine transfusions

Granulocyte or HLA-matched platelet transfusions

Transfusions from blood relatives

Congenital immunodeficiencies

Hodgkin disease

Moderate Risk

Hematologic malignancy (acute myelogenous leukemia/acute lymphocytic leukemia/non-Hodgkin lymphoma)

Patients treated with purine-analog drugs (e.g., chronic lymphocytic leukemia)

Malignancies treated with intensive chemo-/radiotherapy (i.e., neuroblastoma, sarcoma)

Solid organ transplant recipients

Preterm infants

Newborns receiving exchange transfusion

Low/Theoretical Risk

Human immunodeficiency virus/acquired immunodeficiency syndrome

Healthy term newborns

Modified from Schroeder ML. Transfusion-associated graft-versus-host disease. *Br J Haematol* 2002;117:275-287.

Massive Transfusion

Metabolic Effects

Stored blood differs in its composition from that circulating in the body. If large amounts of stored blood are infused rapidly, one may observe adverse effects related to such differences. The elevated K^+ content of stored red cells rarely leads to hyperkalemia, but it is a risk in the presence of renal failure, shock with acidosis, or hemolysis. Plasma contains a significant amount of citrate as anticoagulant; recipients with normal circulatory status promptly metabolize this in the liver, but during plasma exchange or in patients in shock or severe liver failure, citrate excess may lead to hypocalcemia. Hypocalcemic reactions caused by citrate may be treated by intravenous calcium infusion.⁴⁹⁹

Hypothermia

Hypothermia may occur if a large volume of cold blood is infused rapidly. Hypothermia is one of the most common complications of massive transfusion and contributes to the associated coagulopathy. Neonates and the elderly are particularly sensitive to this reaction. Hypothermia affects the way the liver metabolizes citrate, resulting in an increased risk of hypocalcemia. Rapid infusions of citrated blood products in such patients, especially through central venous lines, may lead to arrhythmias. Hypothermia interferes with platelet function and clotting, both of which are improved when the patient is warmed.⁴⁹⁹ One way of approaching this problem is with the use of warmed intravenous fluids or blood. Blood-warming devices are available that can adequately warm the blood administered, even during a rapid and massive transfusion. All patients who are receiving large amounts of red cells and plasma should have those products administered through blood-warming devices. Blood warmers must be checked regularly to ensure that they maintain their temperature. If the blood is overheated, hemolysis and the associated complications of transfusing hemolyzed blood may result.

Any one of these potential problems alone is rarely significant. However, in the critically ill patient who requires massive transfusion, acidosis, hypoxemia, hypothermia, hypocalcemia, and hypo- or hyperkalemia often coexist, with a consequent risk of cardiac arrhythmias. Neonates receiving exchange transfusions are particularly susceptible to such physical and metabolic effects.^{132,500}

Dilutional Coagulopathy

Massive transfusion of one to two blood volumes in patients results, first, in abnormalities of the prothrombin time (PT) and of the activated partial thromboplastin time (APTT); and second, in thrombocytopenia.⁵⁰¹ Massively transfused patients are often affected by sepsis, shock, and intravascular coagulation, which may aggravate the dilutional hemostatic defects.

In practice, most patients tolerate otherwise uncomplicated dilutional coagulopathy well. Factor VIII activity may rise as a response to stress; factor V falls, but rarely to dangerous levels. Moderately severe thrombocytopenia, accompanied in some cases by a significant degree of platelet dysfunction, may be a more significant problem. Transfusion therapy of such patients is best guided by laboratory measurements, but clinical assessment is most important because conventional coagulation tests take time to obtain. As discussed earlier in this chapter, for patients undergoing rapid massive transfusion, the first line of treatment (with regard to hemostatic blood products) should include plasma to correct the levels of coagulation factors, followed by platelet products.^{205,206,208,222,224}

Age of Transfused Blood

In 2008, a study suggested a relationship between the length of blood product storage and the in-hospital mortality of transfused cardiac surgery patients.⁶³ The study was retrospective in nature and elicited much discussion and further investigation. Metaanalyses of studies looking at the effect of age of transfused blood on patient outcomes failed to clarify an association.^{502,503,504} Prospective studies are now ongoing.^{505,506} and ⁵⁰⁷

The changes that stored red blood cells undergo while awaiting transfusion are referred to as the “storage lesion.” In short, these changes are a decrease in both 2,3-diphosphoglycerate, ATP, and an increase in extracellular potassium. Red cell membrane changes result in decreased flexibility of the cell, hemolysis, and formation of microparticles. Whether the red cell storage lesion is responsible for deleterious clinical effects awaits further investigation.

Miscellaneous

Air embolism is a potential hazard when perioperative infusion devices are used.⁵⁰⁸ Fat embolism may occur in the rare situation in which blood products are transfused via the bone marrow. The plastic materials used to ensure the flexibility of some blood storage bags can leach into the product and, although no adverse effects have been demonstrated to date,⁵⁰⁹ attempts are being made to identify alternatives.

Iron Overload: Transfusion Hemosiderosis

Iron overload is a major problem in patients who require longterm red cell transfusion support for chronic anemias due to bone marrow failure.^{510,511} Each unit of red cells contains approximately 0.25 g of iron. After a large number of red cell transfusions, in the absence of blood loss, the recipient develops the stigmata of transfusion siderosis: impaired growth, failure of sexual maturation, myocardial and hepatic dysfunction, hyperpigmentation, and, often, diabetes. Patients such as those with thalassemia who are at risk of this complication should receive prophylactic aggressive iron chelation therapy.

INFECTIOUS COMPLICATIONS OF BLOOD TRANSFUSION

Overview of Blood Donor Screening for Infectious Diseases

In the 1960s, transfusion-associated hepatitis (TAH) occurred in more than 30% of multiply transfused patients. The development and implementation of a screening test for HBsAg and the switch to an all-volunteer blood supply resulted in a dramatic reduction in the incidence of both B and non-A, non-B (NANB) TAH (Fig. 21.7).⁵¹² However, a significant risk of NANB hepatitis persisted.

In the early 1980s, the blood banking industry was further challenged with the appearance of AIDS. In the early and mid-1980s, before the identification of the causative agents of AIDS or NANB hepatitis, the idea of using surrogate tests to identify donations at increased risk of transmitting one of these infections was introduced. Candidate tests included those that would detect the consequences of an infection (e.g., elevated alanine aminotransferase [ALT] in the case of NANB hepatitis or inverted helper-tosuppressor T-cell ratio in the case of AIDS) or those likely to be positive in individuals who engaged in high-risk sexual activity or needle sharing (e.g., antibody to the hepatitis B core antigen [anti-HBc]).^{513,514,515} and ⁵¹⁶ Before the availability of a specific test for HIV, some blood suppliers implemented HBc antibody testing or donor

P.578

T-cell testing in an attempt to reduce the risk of transmitting AIDS through blood transfusion.

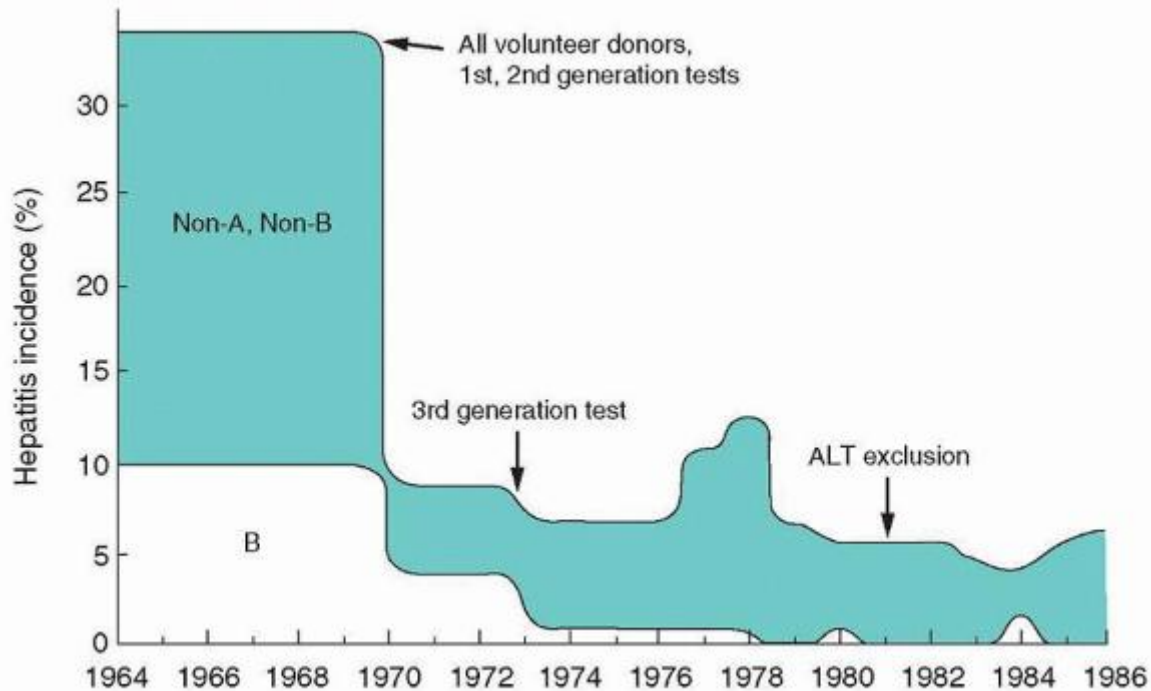

FIGURE 21.7. Annualized incidence of posttransfusion hepatitis B and non-A, non-B at the National Institutes of Health, 1964 to 1986. First-, second-, and third-generation tests refer to tests for hepatitis B surface antigen. ALT, alanine aminotransferase. (Reprinted from Alter HJ. You'll wonder where the yellow went: a 15-year retrospective of posttransfusion hepatitis. In: Moore SB, ed. Transfusion-transmitted viral diseases. Arlington, VA: American Association of Blood Banks, 1987, with permission.)

After the development and implementation of a test for HIV antibody in 1985, it became clear that there is a delay between the onset of infection and the development of detectable antibody. A blood donation made during this “window period” could pass infectious disease screening tests but transmit infection. The FDA required blood centers to inform prospective donors about the window period and to question them directly about specific risk behaviors. Gradually, improvements in the sensitivity of the HIV antibody test led to shortening the HIV window period from 45 days to about 22 days.^{517,518}

During the mid-1980s, surrogate tests for NANB hepatitis and risk activity (ALT and HbC antibody) became required in the United States. A donor screening test for the retrovirus HTLV-I was implemented in 1988. The first donor screening test for antibody to hepatitis C became available in 1990, and an improved test became available in 1992. In 1996, a donor screening test for HIV-1 p24 antigen was implemented because available information suggested that this test could shorten the HIV window period by an additional 6 days.⁵¹⁸ By this time, the risks of transfusion-transmitted HIV and hepatitis were too low to measure prospectively and could only be estimated with the aid of mathematic modeling (Fig. 21.8).^{519,520} and ⁵²¹

FIGURE 21.8. Decline in risk of human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV) transmission by transfusion, 1983 to 2001. Estimates indicated by solid symbols are based on donor prevalence measurements; estimates indicated by shaded symbols are based on recipient follow-up studies; estimates indicated by open symbols represent projections based on mathematical modeling. Estimated risk of infection per unit transfused in 2000-2001 was 1:220,000 for HBV, 1:1.6 million for HCV, and 1:1.8 million for HIV. (From Fiebig E, Busch MP, with permission; modified from Busch MP, Kleinman SH, Nemo GJ. Current and emerging infectious risks of blood transfusions. *JAMA* 2003;289:959-962.)

Despite the extremely low risk of transfusion-transmitted HIV and hepatitis, there continued to be immense public pressure to further improve transfusion safety. In 1999, nucleic acid testing (NAT) for HIV and HCV RNA was added to blood donor screening via clinical trials. Initially available NAT methods were labor-intensive and could not be applied to rapid screening of large numbers of blood donations. NAT screening was rendered feasible by performing the assays on “minipools” of donor specimens (initially pooling 16 to 24 samples together for testing, more recently 6 to 16 samples). Clinical trials of minipool NAT for HIV and HCV RNA confirmed that this testing detects infection earlier than antigen or antibody assays.^{522,523} NAT testing for HIV and HCV RNA is now required by the FDA. With implementation of licensed NAT for HIV, the FDA permitted discontinuation of the HIV p24 antigen test.

NAT assays continue to be improved and new assays developed. Donor NAT assays for HIV and HCV RNA are now fully
P.579

automated and have been multiplexed to include HBV DNA detection. Testing for West Nile virus RNA was initiated in 2003 using investigational assays; this testing is now required by FDA.

Additional donor serologic screening tests have also been developed or are in development. A donor screening assay for antibodies to *T. cruzi* became available in 2007; FDA now requires every donor to be tested once for this infection (see below). Tests for *Babesia* infection are in development.

Residual Risks of Infection

Table 21.10 lists the tests currently performed on volunteer blood donations in the United States. It is thought that the residual risk of transmitting HIV and hepatitis by transfusion is related mainly to window period donations. The probability that a donation was made during the window period can be calculated from the observed incidence of new infections in blood donors and the length of the window period.^{19,521,524} The implementation of nucleic acid testing for HIV and HCV has permitted direct detection of donors with newly-acquired infections (i.e., donors who are NAT-positive, antibody negative). New HIV and HCV infections in repeat blood donors are very rare. However, studies indicate that first-time donors are two to three times more likely than repeat donors to have newly-acquired infection.¹⁹ Thus, current estimates of transfusion risk include an adjustment for a 2- to 3-fold higher probability that a first-time donor is in the window period compared to a repeat donor.^{523,524,525} and ⁵²⁶ Table 21.11 shows the current risk estimates for transfusion-transmitted HIV, HCV, and HBV based on the length of the window period and the estimated frequency of window period donations.

Because the current risks of transmitting HIV and HCV are low, the absolute benefit gained from further incremental improvements in blood donor testing for these infections would be very small. The implementation of individual-unit NAT for HIV and HCV, for example, would be associated with extremely high cost with very little incremental improvement in blood safety in the US.^{527,528} Similarly, the value of processes to chemically inactivate residual pathogens in blood products has been questioned in view of the low residual risks of HIV and HCV. These treatments, however, might represent a reasonable approach toward reducing the risk of transmitting infectious agents for which there are currently no donor screening tests.^{529,530} Some pathogen reduction treatments for platelets and fresh plasma are in use outside the US, but as of April 2012 these were not approved for use in the US. Commercial plasma derivatives are, however, subjected to a solvent/detergent treatment that inactivates lipid-enveloped viruses such as HIV, HCV, and HBV. Solvent/detergent treatment cannot be applied to cellular blood components.

TABLE 21.10 INFECTIOUS DISEASE TESTING PERFORMED ON U.S. BLOOD DONATIONS

Infection	Tests Designed to Detect
Hepatitis B	Hepatitis B surface antigen IgM and IgG antibody to hepatitis B core antigen HBV DNA ^a
Hepatitis C	IgG antibody to hepatitis C peptides Hepatitis C virus RNA ^a
HIV-1/-2	IgM and IgG antibody to HIV-1/-2 HIV-1 RNA ^a
HTLV-I/-II	IgG antibody to HTLV-I/-II
Syphilis	IgM and IgG antibody to treponemal antigens <i>Or</i> nontreponemal serologic reactivity (e.g., rapid plasma reagin)
WNV	WNV RNA ^a
<i>T. cruzi</i>	IgG antibody to <i>T. cruzi</i> ^b

HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus; Ig, immunoglobulin; WNV, West Nile virus.

^a Nucleic acid testing is usually performed on minipools of 6 to 16 donor samples.

^b *T. cruzi* antibody testing may be limited to one-time testing of each donor.

TABLE 21.11 CURRENT ESTIMATED RISKS OF TRANSFUSION-TRANSMITTED INFECTION BASED ON WINDOW PERIOD/INCIDENCE ESTIMATES^a

Agent	Window Period (Days)^b	Incidence of New Infections in Repeat Donors (per 100,000)	Estimated Risk/Unit Transfused^c
--------------	---	---	---

		Person-Years)	
Hepatitis B	38	2.49	1:280,000
Hepatitis C	7.4	2.98	1:1,149,000
Human immunodeficiency virus		2.16	1:1,467,000

^aEstimates are based on figures from Zou S, Dorsey KA, Notari EP, et al. Prevalence, incidence, and residual risk of human immunodeficiency virus and hepatitis C virus infections among United States blood donors since the introduction of nucleic acid testing. *Transfusion* 2010;50:1495-1504⁵²⁵; and Zou S, Stramer SL, Notari EP, et al. Current incidence and residual risk of hepatitis B infection among blood donors in the United States. *Transfusion* 2009;49:1609-1620.⁵²⁶

^b Window-period estimates assume minipool nucleic acid testing for HIV and HCV and no HBV DNA testing.

^c Estimated risk/unit transfused is calculated using an adjustment for the proportion of units from first-time donors, whose incidence of infection is two to four times higher than that of repeat donors.

Modified from Galel S. Infectious disease screening. In: Roback JD, Grossman BJ, Harris T, Hillyer CD, eds. *AABB technical manual*, 17th ed. Bethesda, MD: AABB, 2011:239-270.⁵⁴⁴

Transfusion-associated Hepatitis

Before the development of serologic tests capable of determining the cause of TAH, all TAH was thought to be due to hepatitis B (the “serum hepatitis” agent). After the HBsAg test became available, however, it was discovered that hepatitis B accounted for only about 25% to 30% of TAH cases.^{531,532} Subsequent studies excluded hepatitis A virus (HAV), CMV, and the Epstein-Barr virus (EBV) as common causes of TAH. The designation NANB hepatitis was created to describe the majority of TAH cases.⁵³³ In 1988, the major causative agent of NANB hepatitis was identified as HCV.^{534,535} Widespread testing of all blood donations for this virus was implemented in 1990. An improved test for hepatitis C became available in 1992. Since then, TAH has become rare.

Hepatitis B

The discovery of HBsAg and application of this test to blood donor screening led to a dramatic reduction in transmission of HBV by transfusion (Fig. 21.7).⁵³⁶ Screening of all blood products for HBsAg began in 1970 in the United States with low-sensitivity tests and was made mandatory in 1972. The high-sensitivity HBsAg test in current use becomes positive an average of 38 days after the onset of infectivity.⁵³⁷ This test detects most but not all donors who are infectious for hepatitis B. Three types of individuals with hepatitis B infection may be missed by the current HBsAg test: (1) individuals with early infection whose HBsAg has not yet become detectable; (2) individuals who were previously vaccinated against HBV and have anti-HBs but who acquire HBV infection after subsequent exposure (so-called “vaccine breakthrough” infections);

P.580

and (3) individuals with chronic infection whose HBsAg has fallen below the limits of detection (“occult HBV infection”).

Units from individuals with chronic occult HBV (category 3 above) are currently excluded from the US blood supply by donor testing for anti-HBc. In the US, anti-HBc-positive donations are permitted into pooled plasma derivatives, however, because HBV infectivity is eradicated from these products by the pathogen inactivation processes to which the products are subjected. Based on currently mandated donor screening tests (i.e., HBsAg and anti-HBc), the current estimated risk of HBV transmission by individual blood components in the United States is 1 in 280,000 units⁵²⁶ (Table 21.11).

As of April 2012, HBV DNA testing of blood donors was not required in the US. However, most US blood donors were, in fact, being tested for HBV DNA because probes for this target were included in the donor screening NAT assays used for HIV and HCV RNA detection. In November 2011 the US FDA issued a draft guidance document indicating its intention to make HBV DNA screening a requirement.⁵³⁸ HBV DNA tests detect some, but not all, of the HBV-infected donors missed by

HBsAg testing.⁵³⁹ HBV DNA screening of blood donors has more value in HBV endemic countries where donors are not screened for anti-HBc.⁵⁴⁰

Hepatitis C

Donor screening for HCV includes NAT for HCV RNA as well as HCV antibody testing. It is estimated that the donor RNA test detects infection an average of 7.4 days after exposure. Based on window period/incidence modeling, the risk of HCV transmission by transfusion of fresh blood products is now estimated to be approximately 1 in 1,149,000 (Table 21.11).⁵²⁵

Hepatitis A Virus

Transfusion-related transmission of HAV by fresh blood products is rare.^{541,542} However, transmission of HAV has been associated with pooled plasma products.⁵⁴³ Because HAV is not lipid-enveloped, infectivity is not eliminated by solvent/detergent treatment. Therefore, immunization to HAV is recommended for patients who are expected to receive pooled plasma products, such as those with clotting disorders.⁵⁴³ The FDA does not require donor screening for this agent. Some plasma-derivative manufacturers, however, test plasma pools for HAV nucleic acid in an effort to reduce the risk of transmitting this agent.

Human Immunodeficiency Virus Type 1 and Type 2

Current donor screening for HIV includes nucleic acid testing for HIV-1 RNA and testing for antibodies to HIV-1 and HIV-2. The window period for HIV, based on time to detection of RNA via minipool nucleic acid screening, is currently estimated at 9 days.⁵²⁵ The current estimated risk of HIV transmission by transfusion is approximately 1:1,467,000 units (Table 21.11). Donor questioning regarding HIV risk behavior and the temporary exclusion of individuals at increased risk of being in the HIV window period are critical and essential elements of this safety level.⁵⁴⁴ Whether certain deferral periods could be shortened without compromising blood transfusion safety has been the topic of intense public discussion.⁵⁴⁵

Other Infections

Essentially any infection that can circulate in the blood of an apparently healthy blood donor can be transmitted by transfusion. Recently, the AABB's Transfusion-Transmitted Diseases (TTD) Committee evaluated a number of potentially transmissible infections, their risks of causing severe disease, and the need for intervention strategies.⁵⁴⁶ This analysis is available online and is updated periodically. Some of the agents that have been the focus of recent interventions or public debate are discussed below.

Infections Transmitted by Arthropods

Over the past decade, much attention has been focused on infectious agents that can be transmitted to donors by insects and further transmitted to patients via transfusion.⁵⁴⁶ This category of pathogens includes West Nile virus, *Trypanosoma cruzi*, babesia, malaria, and dengue fever.

West Nile Virus

West Nile virus was first detected in the United States in 1999, and has since spread through the North American continent in annual epidemics. Birds are the natural reservoir of the virus, which is spread to humans by mosquitos.⁵⁴⁷ Eighty percent of infected individuals are asymptomatic, 20% have a relatively nonspecific febrile illness, and <1% develop neuroinvasive disease (meningitis, encephalitis, or flaccid paralysis), which can lead to chronic disability or death.

WNV was first demonstrated to be transmissible by transfusion in 2002, when infection in 23 recipients was linked to blood components later found to contain WNV RNA but no WNV antibody.⁵⁴⁸ In 2003, minipool NAT screening of blood donations for West Nile virus RNA was implemented throughout the United States using investigational assays. WNV NAT assays are now FDA-approved and required. Transmissions despite minipool donor testing led to the discovery that 20% to 30% of donors with WNV infection may be missed by minipool testing because of low levels of circulating virus.^{549,550} Therefore, at times of high WNV activity, donor WNV RNA screening must be performed on individual donations.⁵⁵¹

Malaria

Malaria is a common infection globally. However, transfusion-transmitted malaria is rare in the United States, with only zero to three cases per year occurring during the last decade.⁵⁵² This degree of safety is remarkable considering that there is no donor screening test for malaria in the United States. Screening is accomplished entirely by donor questioning. According to current FDA guidelines, individuals are deferred from donation for 1 year after travel to a malarious area and for 3 years after living in a malarious area. Almost 3% of otherwise eligible donors are excluded on the basis of this questioning. Of the donors implicated in the recent cases of transfusion-transmitted malaria in the United States, approximately 60% (including the majority of *Plasmodium falciparum* infections) should have been excluded by donor

deferral criteria. The remaining cases are largely related to chronic asymptomatic infections in donors who are beyond the deferral period.⁵⁵²

Babesiosis

Babesiosis is caused by a protozoan parasite that infects human RBCs. It is transmitted by the Ixodes tick, the same vector that transmits the causative agents of Lyme disease and human granulocytic anaplasmosis. US cases of babesiosis were first identified in the northeast United States but have now also been identified in Minnesota, Wisconsin, and California.⁵⁵³

Incubation ranges from 1 to 6 weeks or longer. Symptoms range from none to mild flulike symptoms to a malaria-type illness with hemolytic anemia. Asymptomatic individuals may remain infective for months or years.⁵⁴⁶ More than 150 cases of transfusion-transmitted babesiosis have been identified, including fatalities. Asplenic, immunocompromised, and elderly patients appear to be at increased risk for severe infection. It is suspected

P.581

that transfusion-transmitted babesiosis is vastly underrecognized. The need for an intervention to reduce transfusion-transmitted babesia in the US has been acknowledged at the national level.^{553,554} Antibody screening of donors or pathogen reduction could theoretically reduce transmission, but there is currently no intervention approved for use.

Lyme disease is caused by the spirochete *Borrelia burgdorferi* and is transmitted by the same tick vector that transmits babesiosis. The organism has been found to survive the storage conditions of RBC and platelet components. Nevertheless, there have been no documented cases of transfusion-transmitted Lyme disease.⁵⁴⁶

Trypanosoma cruzi

Trypanosoma cruzi, the protozoan parasite that causes Chagas disease, is endemic in portions of Mexico, Central America, and South America. It is transmitted to humans by the reduviid bug. Acute infection is usually self-limited, although rarely it may involve myocarditis or meningoencephalitis and may be fatal, particularly in immunocompromised patients. In most cases, however, the acute infection goes undiagnosed, and the infection becomes chronic. After decades, 20% to 30% of chronically infected individuals develop cardiac or intestinal dysfunction that can be fatal. The transmission of *T. cruzi* by transfusion is well documented in endemic areas.⁵⁴⁶ A blood donor screening assay for *T. cruzi* antibody became available in the US in 2007. The vast majority of the infected donors detected have been immigrants from endemic areas; US-acquired *T. cruzi* appears to be rare. Therefore, the FDA has endorsed a strategy of testing each US donor only once for this infection.³¹

Dengue Virus

Studies in dengue-endemic regions outside the continental US have documented a high prevalence of blood donors with asymptomatic viremia during dengue outbreaks.⁵⁵⁵ Concern about this virus in the US has increased recently with recognition of infections in the southern part of the country.⁵⁵⁶ Although there does not currently appear to be a need for blood donor screening for this virus within the continental US, activity of this virus will need to be monitored.

Transmissible Spongiform Encephalopathies: Creutzfeldt-Jakob Disease and Variant Creutzfeldt-Jakob Disease

Both classical Creutzfeldt-Jakob disease (CJD) and variant Creutzfeldt-Jakob disease (vCJD) are rapidly progressive fatal infections of the nervous system caused by prions.⁵⁴⁶ Individuals at increased risk for classical CJD are currently excluded from blood donation in the United States, despite evidence that this disease is not transmissible by transfusion.⁵⁴⁶

In contrast, variant CJD (vCJD) does appear to be transmissible by transfusion. Human vCJD is caused by the same prion that causes bovine spongiform encephalopathy (BSE), or "mad cow disease." As of April 2012, four cases of apparent transfusion-transmitted vCJD had been identified in the UK, where a BSE epidemic occurred between 1980 and 1996. In addition, one case of vCJD had been identified postmortem in a hemophilia patient in the UK who died of other causes. Worldwide, steps have been taken in an effort to minimize the risk of vCJD transmission by blood products in the absence of a donor screening test for the infection. In the United States, individuals are currently excluded from donating blood if they lived in the UK for 3 months or more between 1980 and 1996, if they lived in Europe for 5 years or more since 1980, or if they received a transfusion in the UK or France since 1980.⁵⁵⁷ Filters that may absorb prions are in development, and attempts to develop blood donor screening tests are also underway.⁵⁴⁶ Because prions lack lipid coats and nucleic acid, the causative agent of vCJD would not be inactivated by any of the pathogen inactivation processes currently in use or under development.

Bacterial Contamination

Bacteria are present in approximately 1/3,000 cellular blood components.⁵⁵⁸ Potential sources of bacteria include asymptomatic bacteremia in the donor and bacteria from the donor's skin. Bacterial contaminants multiply fairly readily in platelet components, which are stored at room temperature, but less readily in red cell products, which are refrigerated.

Recognition of morbidity and mortality from transfusion of bacterially contaminated platelets prompted the AABB to implement, in 2004, a requirement for bacterial testing of platelet components. AABB now also requires diversion of the first several milliliters of donor blood into a sample pouch to reduce contamination of platelet units by skin contaminants.⁵

The quantity of bacteria in blood components just after collection is too low to detect by any diagnostic assay. The platelet bacterial screening process used by most US blood centers involves a 36 to 48 hour quarantine of the platelet components. First, there is a 24-hour hold after collection to allow potentially contaminating bacteria to multiply to detectable levels. Then, a sample is taken from each product and inoculated into a blood culture bottle. If the culture is negative after 12 to 24 hours, the product is made available for use, but the culture is continued for the shelf life of the unit. About 1 in 5,000 apheresis platelets are found by this screening to be bacterially contaminated.⁵⁵⁹ This screening process is imperfect, however, and still fails to detect some bacterially contaminated platelets. Recently, a strip immunoassay which could be used by hospitals to retest platelets was reported to find bacteria in approximately 1 in 3000 pheresis platelets that had been negative on their culture screen.⁵⁶⁰ This immunoassay or alternative tests are associated with false positives and logistical challenges, however, and still fail to detect some contaminated products.⁵⁶¹ Given the imperfections of current platelet screens, and the lack of any bacterial screen for red cell products, bacterial contamination must remain in the differential diagnosis when transfusion recipients become febrile or hypotensive following transfusions. The pathogen inactivation systems in development for cellular blood components all appear likely to inhibit the growth of bacteria.⁵⁶²

Cytomegalovirus

CMV is a DNA virus in the herpesvirus family.⁵⁶³ Like other herpesviruses, it remains latent after acute infection, with the potential for reactivation.

In immunologically normal adults, CMV disease manifestations range from none to a mononucleosis-like syndrome. In immunosuppressed or immunodeficient patients, however, both primary and reactivation disease may be associated with overwhelming manifestations including thrombocytopenia, hemolytic anemia, pneumonitis, colitis, hepatitis, meningoencephalitis, and death. Effective antiviral treatment is available. The incidence of severe disease can be reduced by prophylactic treatment of high-risk patients with antiviral drugs or by careful monitoring of such patients and initiation of therapy with the first evidence of infection.⁵⁶³

CMV is transmitted only through cellular blood components. The incidence of transmission of CMV by transfusion appears to be low (<1%) in immunologically normal recipients.⁵⁶⁴ Immunodeficient patients, however, are at increased risk of acquiring CMV from transfusion. CMV transmission to these patients can be greatly reduced by restricting their cellular

P.582

components to products obtained from CMV-seronegative donors or by use of leukoreduced blood components.⁵⁶³ Most studies have detected no transmission of CMV by leukoreduced blood components. Some transmissions were detected, however, in a large randomized study that evaluated the incidence of CMV infection and CMV disease in 502 bone marrow transplant recipients randomized to receive either leukoreduced (i.e., leukofiltered) or CMV antibody negative blood components.⁵⁶⁵ CMV infection was observed in 1.3% of recipients of seronegative components and in 2.4% of recipients of leukoreduced components, a difference that was not statistically significant. However, in the leukoreduced arm, all CMV-infected patients developed disease, and five out of six died; in the serologically screened arm, there were no cases of CMV-related disease or death. A meta-analysis estimated that the risk of transfusion-transmitted CMV is approximately 1.5% with use of CMV antibody-screened components, compared to 2.5% with leukoreduced, antibody-unscreened components.⁵⁶⁶ Most of the cellular components in the US are leukoreduced. Whether it is clinically beneficial to perform CMV antibody screening in addition to leukoreduction remains controversial.⁵⁶³

It is generally recommended that cellular products with a reduced risk of transmitting CMV (leukoreduced or CMV antibody negative) be used for patients at increased risk of severe primary CMV disease, including unborn babies (i.e., intrauterine transfusion), low-birth-weight infants of seronegative mothers, seronegative recipients of seronegative solid organ or HPC transplants, and seronegative patients with severe cellular immunodeficiency (e.g., HIV-infected patients). Products with reduced CMV risk are often provided also for seronegative patients who are likely to require transplantation in the future, in order to reduce their future risk of CMV-reactivation disease.⁵⁶³

There is no clinical benefit of providing products of reduced CMV risk to patients who are already seropositive. Although second-strain infections may occur, these have not been shown to be clinically important given the high risk of reactivation disease these patients face. In CMV-positive recipients of allogeneic hematopoietic progenitor cell transplants, the use of CMV-positive stem cell donors has no detectable adverse effect on patient outcomes.⁵⁶⁷ Therefore, it seems that CMV-seropositive blood components would also be acceptable in this setting.

Seronegative recipients of seropositive organ and stem cell transplants are at high risk of CMV disease⁵⁶⁸ and are likely to be monitored closely, treated prophylactically, or both. It is unclear whether providing blood products with reduced CMV risk to such patients is of clinical benefit.

Pathogen Reduction Technologies

Donor screening and testing cannot completely eliminate the possibility of transfusion-transmitted infection or blood product contamination. The ideal pathogen reduction technology (PRT) would effectively inactivate residual pathogens without adversely affecting the function, toxicity, or immunogenicity of the blood component. Most commercial plasma derivatives are treated with heat and/or organic solvents and detergents (SD). SD treatment inactivates lipid-coated agents. Cellular blood components, however, cannot withstand this treatment. Most of the PRTs in development for cellular products consist of blood product additives that bind to and damage DNA and thereby prevent residual pathogens from proliferating in the blood component or in the recipient. These treatments would theoretically also prevent transfusion-related GVHD because the DNA of WBCs in the blood product would also be affected. The efficacy of PRT agents is dependent on their ability to penetrate cellular membranes or viral envelopes and reach the target nucleic acid. Because of concern that DNA-altering agents could cause long-term toxicity in transfusion recipients, many of the PRT systems include processes that remove the DNA-binding agent or inactivate it. PRTs in distribution outside the US and in development have been recently reviewed.^{530,562} Examples are listed in Table 21.12.

PRTs can reduce the residual risk related to window period transmissions of HIV, HCV, and HBV, but these risks are small. The primary benefit of PRTs is to reduce transmission of agents for which there are currently no tests.⁵²⁹ These treatments are costly. The incremental costs of PRT can be offset if they are approved by regulators as eliminating the need for irradiation, CMV antibody screening, and bacterial testing.⁵²⁹ Elimination of platelet bacterial testing would also expedite release of these products.

Several PRT systems for plasma are in use outside the US. One (S/D plasma) is a commercial product manufactured from pools of donor plasma. A pooled product has both theoretical advantages and disadvantages. For example, pooling dilutes antibodies from individual donors and thereby theoretically reduces the risk of antibody-mediated transfusion complications such as TRALI. However, pooling could increase a recipient's risk of exposure to an emerging pathogen that is not removed or inactivated by the manufacturing process. PRTs that involve treatment of individual plasma units are more logistically challenging. All of the plasma PRTs listed in Table 21.12 have been determined to satisfy the Council of Europe plasma quality standards.

As of April 2012, the amotosalen/UV and riboflavin/UV PRTs for platelet products were in distribution in some countries outside of the US. Both of these treatments appear to be associated with some loss of platelet product potency.^{101,102} The clinical importance of the potency changes relative to the theoretical benefit of PRT is unclear.

THERAPEUTIC APHERESIS

Therapeutic apheresis is an important modality of therapy in the management of several diseases.^{30,569,570,571,572,573,574} and ⁵⁷⁵ The term plasmapheresis refers to the selective removal of plasma. This includes the collection of plasma from normal donors. A therapeutic plasma exchange, on the other hand, refers to the removal of a large proportion of a patient's plasma and replacement with crystalloid or colloid fluids and/or plasma product. These terms are often used interchangeably. Therapeutic cytapheeresis, the removal of red cells, leukocytes, or platelets, is used infrequently in the

management of patients with hemoglobinopathies, leukostasis, or thrombocytosis, respectively.

TABLE 21.12 PATHOGEN REDUCTION TECHNOLOGIES FOR TRANSFUSABLE BLOOD COMPONENTS

Component	Technology	Manufacturer
Plasma: commercially prepared pools	• Solvent/detergent treatment	Octapharma
Plasma: individual units	• Amotosalen (psoralen) + UV light	Cerus

	• Riboflavin (vitamin B2) + UV light	Terumo BCT
	• Methylene blue + light	MacoPharma
Platelets	• Amotosalen (psoralen) + UV light	Cerus
	• Riboflavin (vitamin B2) + UV light	Terumo BCT
	• UV light	MacoPharma
Red Blood Cells	• Frangible nucleic acid crosslinker	Cerus
Whole Blood	• Riboflavin (vitamin B2) + UV light	Terumo BCT

Modified from Galel S. Infectious disease screening. In: Roback JD, Grossman BJ, Harris T, Hillyer CD, eds. AABB technical manual, 17th ed. Bethesda, MD: AABB, 2011:239-270.⁵⁴⁴

Guidelines for clinical practice have been developed by the American Society for Apheresis (ASFA) and are regularly updated every 3 to 7 years with a systematic review of the medical literature. The current guidelines published in 2010⁵⁷⁶ review the therapeutic apheresis procedures most commonly performed (i.e., therapeutic plasma exchange (TPE), red blood cell exchange, erythrocytapheresis, thrombocytapheresis, leukocytapheresis, extracorporeal photopheresis (ECP), immunoadsorption (IA), selective removal methods, adsorptive cytapheresis, and membrane differential filtration. Additionally, the guidelines contain 59 specific disease fact sheets listing the type of apheresis procedure to be performed and the rationale for it, the recommended blood volume to be exchanged, and the duration of the treatment.

The disorders for which therapeutic apheresis has been used are divided into four categories: category I, for which apheresis is the accepted first line of therapy; Category II, for which apheresis is considered a second-line therapy, after a patient has failed or is unable to undergo the first-line therapy; category III, for which the optimum role of apheresis therapy is not established and decision making should be individualized; and category IV disorders, in which published evidence demonstrates or suggests apheresis to be ineffective or harmful.^{570,576,577} Some of the indications for TPE (categories I and II) are listed in Table 21.13.

Therapeutic Plasma Exchange

Indications

The therapeutic goal of therapeutic plasma exchange (TPE) is to remove plasma components such as monoclonal proteins and cryoglobulins,⁵⁷³ immune complexes,⁵⁷¹ lipoproteins, or toxins⁵⁷³ responsible for physical or metabolic problems. These may include removal of autoantibodies, as in myasthenia gravis⁵⁷⁴ and Goodpasture syndrome⁵⁷³; or alloantibodies, as in posttransfusion purpura or patients with Factor VIII inhibitors.⁵⁷² The existence and pathogenic role of antibodies or immune complexes are presumed in several situations often treated with TPE, including neurologic disorders such as Guillain-Barré syndrome,^{569,574,578,579} and⁵⁸⁰ polyneuropathy,⁵⁷⁴ and various nephritides.^{573,581} In thrombotic thrombocytopenic purpura (TTP), TPE using cryoprecipitate-reduced plasma⁵⁸² or frozen plasma as the replacement fluid serves to either replace the missing vWF-cleaving metalloprotease or to remove autoantibodies to this protein.^{118,583} TPE or plasma transfusion^{584,585} and⁵⁸⁶ may be life-saving in this disease, as it controls the microangiopathy.

TABLE 21.13 SOME INDICATIONS FOR THERAPEUTIC PLASMA EXCHANGE

Accepted as Therapy (Category I)

Thrombotic thrombocytopenic purpura

Posttransfusion purpura

Guillain-Barré syndrome

Myasthenia gravis

Chronic inflammatory demyelinating polyneuropathy

Goodpasture syndrome

Refsum disease

Accepted as Supportive Therapy (Category II)

Cold agglutinin hemolytic anemia

ABO-incompatible marrow transplant

Cryoglobulinemia

Lambert-Eaton myasthenic syndrome

Rapidly progressive glomerulonephritis

Autoimmune thrombocytopenia

Myeloma and Waldenström macroglobulinemia, and other paraproteinemias with renal failure or hyperviscosity

Coagulation factor inhibitors

Familial hypercholesterolemia

Technical Considerations

The amount of plasma to be removed from the patient is determined by the physician, depending on the clinical situation. A patient's plasma volume may be estimated at 40 ml/kg, determined from a nomogram based on the patient's sex, height, weight, and hematocrit⁵⁸⁷; or estimated according to the weight and hematocrit by the following formula:

Circulating blood volume = patient weight (kg) × 70 ml/kg.

Circulating plasma volume = circulating blood volume × (1.0 - hematocrit [expressed as a decimal]).

TPE is typically performed with 1.0 to 1.5 plasma volume exchanges or approximately 3,000 to 4,500 ml. If <1,000 ml is removed from an adult, it may be possible to replace the loss with crystalloid alone; if a more extensive plasma exchange is performed, use of a colloid is necessary. Albumin (5%) is the replacement fluid most commonly used in the United States. FFP or FP24 is indicated in certain instances, such as TTP or as a component of the replacement fluid in the setting of a coagulopathy.

After exchange of one plasma volume, approximately 62% of the original plasma has been removed. The efficiency of plasma exchange decreases with further exchange (Table 21.14).

In practice, measurement of plasma protein concentrations after exchange has confirmed the approximate validity of these estimates. However, efficacy varies with the plasma factor to be removed. IgM and fibrinogen, which are largely confined to the intravascular space, are removed most efficiently.^{588,589} and ⁵⁹⁰ IgG is removed less efficiently by plasma exchange because only 45% to 50% of the body's IgG is located in the intravascular space, although IgG levels can be reduced by repeated TPE. Patients receiving plasma exchange for immunologic diseases generally have 1.0 to 1.5 plasma volumes exchanged at each procedure; this is often repeated, for a total of 5 to 7 exchanges over a period of 7 to 10 days. Such plasma exchange schedules have been determined empirically; the optimal exchange regimens for different diseases are unknown.

Therapeutic Cytapheresis

Therapeutic leukapheresis is used in the treatment of patients with leukostasis as a result of extremely high circulating concentrations of immature cells.^{572,591,592} At blast counts $>100 \times 10^9/L$, there is an increasing risk of cerebral and pulmonary leukostasis, resulting

P.584

in impaired capillary blood flow resulting from obstruction of small vessels. This situation may be encountered in the acute leukemias but rarely in chronic lymphocytic leukemia or chronic myelogenous leukemia. Therapeutic leukapheresis decreases the circulating blast count more rapidly than chemotherapy alone; chemotherapy must be instituted promptly once the patient is stabilized, to prevent rebound leukocytosis. The only exception is in pregnancy, in which leukapheresis may be indicated until after the delivery of the fetus, thereby protecting the fetus from the teratogenic effects of chemotherapy.

TABLE 21.14 PLASMA EXCHANGE: THEORETICAL EFFICIENCY

Number of Plasma Volumes Exchanged Percent (%) of Original Plasma Remaining

0.5	60
1.0	38
1.5	22
2.0	15

Therapeutic leukapheresis has also been used in the treatment of patients with other leukemic diseases, such as chronic lymphocytic leukemia that is resistant to drugs, Sézary syndrome, and hairy cell leukemia, and as maintenance therapy in chronic myelogenous leukemia. However, it has not found a distinct role in such conditions.^{572,592,593} Collection of leukocytes by apheresis, followed by ex vivo exposure of the leukocytes to UV light in the presence of a psoralen, and reinfusion of the treated leukocytes ("photopheresis") has become standard therapy for cutaneous T-cell lymphoma. This procedure may be useful in the treatment of other disorders such as GVHD.⁵⁹²

Therapeutic plateletpheresis^{572,594,595} is performed very rarely and is not considered to be first-line therapy. It is indicated in patients with very high platelet counts, usually >1.0 to $1.5 \times 10^{12}/L$, in whom the high count is directly responsible for serious thrombotic or hemorrhagic problems, or in whom other urgent clinical situations necessitate immediate lowering of the platelet count. Therapeutic plateletpheresis must be followed by cytotoxic therapy to prevent rebound after the procedure, or its effect is very short-lived.

Erythrocytapheresis (red cell exchange) is used in sickle cell disease to replace sickled cells with normal erythrocytes and thereby prevent thromboses and improve capillary circulation.⁵⁷² Stroke prevention by maintaining hemoglobin S level below 30% and acute chest syndrome are the two major indications for red cell exchange in patients with sickle disease.⁵⁷⁶

Therapeutic Absorption of Plasma Constituents

Apheresis technology may be used to selectively remove constituents of plasma implicated in disease processes. In these procedures, a patient's plasma is withdrawn and separated by apheresis technology, passed over a selective absorption column, and reinfused into the patient. This technique has been used to selectively remove IgG (staphylococcal protein A columns) or low-density-lipoprotein (LDL) cholesterol.⁵⁹² Selective apheresis may specifically treat diseases such as LDL-hypercholesterolemia. Patients with LDL-hypercholesterolemia are at risk of developing severe coronary artery disease despite a low-fat diet and cholesterol-lowering agents. Selective LDL apheresis involves separation of the patient's plasma, followed by selective removal of apoB-containing atherogenic lipoproteins, preserving the cardioprotective HDL cholesterol, after which the cleansed plasma is recombined with the cellular portion of the blood and returned to the patient. This procedure was shown to be safe and efficacious in controlling patients with familial hypercholesterolemia.⁵⁹⁶

Adverse Effects

Adverse reactions to therapeutic apheresis are common but usually mild.^{597,598} and ⁵⁹⁹ In a 1-year period in Canada, there were side effects in 12% of more than 5,235 procedures in 627 patients.⁵⁹⁸ They included vasovagal reactions, fluid imbalance with hypovolemia or overload, fever, chills, and hypocalcemic citrate reactions ranging from paresthesias to arrhythmias. If plasma is used as the replacement fluid, urticarial reactions may be encountered. Mild dilutional coagulopathy and thrombocytopenia occur but are rarely significant.^{600,601} Problems related to venous access are common. The possibility of immunologic rebound after plasma exchange has been suggested but has not been observed clinically,^{602,603} perhaps because many patients so treated are also receiving immunosuppressive agents for the underlying diseases. Infections related to indwelling venous lines are not uncommon. Deaths have been reported with therapeutic apheresis.^{597,599,604} It is important that patients be carefully assessed and the indications reviewed before implementing this form of therapy.

SUMMARY

Blood transfusion is an essential component of therapy for a wide variety of disorders. The menu of blood components and the technologies for collecting, processing, and screening blood are constantly changing. Collaboration between transfusion medicine professionals and patient care teams ensures the most appropriate application of blood transfusion therapies.

Acknowledgments

The authors wish to thank Judy Kawamoto for providing the technical and organizational expertise that was essential to the preparation of this manuscript.

Chapter 22

Anemia: General Considerations

Robert T. Means, Jr.

Bertil Glader

This introductory chapter focuses on the general concepts of anemia, the classification of the most common types of anemia, the approach to patients with hemolysis, and the assessment of posthemorrhagic anemia. Anemia rarely is a disease by itself; almost always it is a sign of an acquired or genetic abnormality. The various medical conditions that lead to anemia encompass nearly the full spectrum of human disease.

DEFINITION OF ANEMIA

Red blood cells (RBCs) circulate in the peripheral blood for 100 to 120 days, and approximately 1% of the body's red cells are lost and replaced each day. Red cells recognized as being old are removed from the circulation by macrophages in the spleen, liver, and bone marrow (Chapter 6). An erythropoietic feedback loop ensures that the total red cell mass remains constant. A reduced RBC mass results from loss of RBCs from the circulation at a rate greater than their production: this may reflect increased RBC clearance, decreased RBC production, or both.

Anemia is functionally defined as an insufficient RBC mass to adequately deliver oxygen to peripheral tissues. For practical purposes, any of the three concentration measurements performed on whole blood can be used to establish the presence of anemia: the hemoglobin (Hb) concentration, typically expressed as grams Hb per deciliter (g/dl) in the United States and as grams per liter in Europe; the hematocrit (Hct; also called the packed cell volume [PCV] or volume of packed red blood cells [vPRC]), which represents the proportion of blood volume represented by RBCs, expressed as a percent or as a decimal; and the RBC concentration in cells per microliter ($10^6/\mu\text{l}$) in the United States or per liter ($10^{12}/\text{L}$) by international terminology.

In the past, these parameters were measured using manual physical and chemical techniques. The term “hematocrit” originally referred to the graduated tube in which the vPRC was measured following centrifugation. Now these parameters are determined by electronic cell counters and Hb analyzers (Chapter 1). In most of the current analyzers, RBC concentration, Hb concentration, and mean corpuscular volume (MCV in fl) are directly measured. These measured values are used to calculate the hematocrit (Hct), mean corpuscular Hb (MCH), and mean corpuscular Hb concentration (MCHC):

$$\text{Hct (\%)} = \text{MCV (fl)} \times \text{RBC (}10^6/\mu\text{l)} / 10$$

$$\text{MCH (pg)} = \text{Hb (g/dl)} \times 10 / (\text{RBC (}10^6/\mu\text{l)})$$

$$\begin{aligned} \text{MCHC (\%)} &= \text{Hb (g/dl)} \times 100 / \text{Hct (\%)} \text{ concentration} \\ &= \text{MCH (pg)} \times 100 / \text{MCV (fl)}^1 \end{aligned}$$

Most physicians prefer to define anemia using the Hb concentration, although for practical purposes the Hct is comparably reliable. The electronic counters also generate an index of red cell size, the red cell distribution width (RDW). The RDW is a quantitative measure of the variation in red cell size, and the higher the value, the more heterogeneous the RBC population size. The mean normal Hb and Hct values and the lower limits of the normal ranges of these parameters depend on the age and gender of the subjects, as well as their altitude of residence.

Anemia in Adults

Many references consider Hb concentrations of 14 g/dl and 12 g/dl as the lower limits of normal, at sea level, in adult men and women, respectively, particularly in the industrialized world.² These values have received wide acceptance and often are used in population surveys.³ However, data from a large, diverse, and carefully selected sample suggest that these values are somewhat high. The sample studied during the second National Health and Nutrition Examination Survey (NHANES II), 1976-1980, was selected statistically as representative of the entire population of the United States.⁴ Age, gender, and race, as well as geographic and socioeconomic factors, were figured into the selection process. For the purpose of determining normal values, subjects were excluded if they were pregnant, if a hereditary hemoglobinopathy was detected, or if the transferrin saturation, MCV, or erythrocyte protoporphyrin value was abnormal. By these means, iron deficient subjects were effectively excluded. The values of the remaining 11,547 subjects were used to calculate a 95% reference range. In adult subjects (age 10 to 44 years), the lower limit of normal was 13.2 g/dl in men and 11.7 g/dl in women (Fig. 22.1). Values for African-American subjects were approximately 0.5 to 0.6 g/dl lower than those of Caucasian subjects. Consistent with these observations, the World Health Organization (WHO) defines the lower limit of normal for Hb concentration at sea level to be 12.0 g/dl in women and 13.0 g/dl in men.⁵

P.588

FIGURE 22.1. The lower limit of normal blood hemoglobin concentration in men and women of various ages. Values were calculated from a sample of 11,547 subjects selected to represent the population of the United States. Subjects with iron deficiency, pregnancy, or an abnormal hemoglobin value were excluded from the sample. (Data from Dallman PR, Yip R, Johnson C. Prevalence and causes of anemia in the United States, 1976 to 1980. *Am J Clin Nutr* 1984;39(3):437-445.)

Hemoglobin Values in the Elderly

Anemia is a common condition in the older population. In a community dwelling American population of individuals over 65 years, 8.5% have a Hb concentration meeting the WHO definition of anemia.⁶ Other investigators have confirmed that the prevalence of anemia rises steadily with age, increasing from approximately 10% in individuals 65 years and older to 20% in individuals over 85 years.⁷ It is a significant predictor of morbidity, mortality, and performance status in the elderly, whether considered as a general risk factor or in the setting of a specific clinical circumstance, such as heart failure.^{8,9,10} and¹¹ While clinical conditions such as iron deficiency, B12 or folate deficiency, the decline in testosterone production in male aging,¹² and the impact on EPO production of the routine decline in creatinine clearance with advancing age,⁸ are likely responsible for a majority of cases, the etiology of a significant proportion of these anemias cannot be readily explained.⁷ Studies of the development of otherwise unexplained anemia in the aging population have suggested the involvement of a number of possible mechanisms, from an increased incidence of underlying diseases which may be associated with cytokine activation and the anemia of chronic disease,^{13,14} to changes in the hematopoietic reserve^{15,16} or even in the characteristics of hematopoietic progenitors themselves.¹⁷ Taken together, slightly lower limits of normal Hb concentration may be applicable in evaluating the elderly. However, the too-easy acceptance of mild anemia as a physiologic phenomenon in the elderly runs the risk of ignoring a potentially valuable early clue to an important underlying disorder.

Hemoglobin Values in Infants and Children

At the other extreme of life, the definition of anemia in infancy and childhood is different from that in adults. The lower limit of normal Hb concentration at birth is 14 g/dl, and this decreases to 11 g/dl by 1 year of age. This Hb decrement, referred to as the physiologic anemia of infancy, occurs as part of the normal physiologic adaptation from the relatively hypoxic intrauterine existence to the well-oxygenated extrauterine environment (Chapter 43). Also, as fetal erythropoiesis is replaced, the MCV decreases from birth (100 to 130 fl) to 1 year of age (70 to 85 fl).

Even after the first year of life, normal childhood Hb and MCV values remain considerably lower than those occurring in adolescents and adults (Table 22.1). From the NHANES II study, the lower limit of normal Hb concentration in both male and female children aged 1 to 2 years was 10.7 g/dl, and the value rose with advancing age until adult levels were reached at age 15 to 18 years.

There has been no completely satisfactory explanation for these differences in normal Hb values of children and adults, but it is not due to nutritional deficiencies. Interestingly, it has been demonstrated that serum inorganic phosphate is 50% higher in children compared to adults, and this hyperphosphatemia is associated with elevated erythrocyte adenosine triphosphate and 2,3-diphosphoglycerate content, and thus the erythrocyte oxygen affinity is decreased in children compared to adults. On this basis, it has been postulated that lower Hb values in children may be due to altered Hb-oxygen affinity and may thereby represent a physiologic anemia of childhood.¹⁸

At puberty, the Hb concentration in children reaches the same levels seen in adults. The higher Hb levels in males presumably are a reflection of the effects of androgens on erythropoiesis.

Limitations in the Use of Hemoglobin Concentration, Hematocrit, and Red Blood Cell Measurements in Defining Anemia

For practical purposes, the blood Hb and Hct determinations are equally useful in assessing for anemia in most patients, but there are limitations that must be recognized:

- Hb and Hct changes may reflect altered plasma volume, not a change in RBC mass (Table 22.2). In pregnancy, for example, the plasma volume increases, thereby decreasing the Hb concentrations, although in fact, total RBC mass actually is increased, but to a lesser degree than the plasma volume.^{19,20,21,22} Similarly, individuals with massive splenomegaly may have some anemia because of hypersplenism, but the degree of anemia may appear more severe because of an increased plasma volume. Conversely, burn patients lose plasma, not RBC, through the injured skin, leaving Hb and Hct concentrated at a higher level. Other causes of dehydration with depletion of intravascular space also produce a spuriously high Hb concentration. In chronically ill patients with a reduced red cell mass, the magnitude of anemia may be masked by an associated contraction of the plasma volume.^{23,24,25,26,27}
- Another consideration is that Hb and Hct changes may reflect underlying physiologic conditions with different oxygen

P.589

needs. For example, chronically hypoxemic subjects, such as individuals who live at high altitudes or patients with a right-to-left cardiac shunt, are typically polycythemic with elevated Hb/Hct levels. A normal Hb/Hct level in such a patient actually may represent anemia by the functional criterion of adequately meeting tissue oxygen requirements.

TABLE 22.1 RED BLOOD CELL CHARACTERISTICS IN CHILDHOOD

Age	Lowest Normal Hb (g/dl)	Normal Red Blood Cell Size Mean Corpuscular Volume (fl)	Fetal Hb (%)
Birth	14.0	100-130	55-90
1 mo	12.0	90-110	50-80
2 mo	10.5	80-100	30-55
3-6 mo	10.5	75-90	5-25
6 mo-1 y	11.0	70-85	<5
1-4 y	11.0	70-85	<2
4 y-puberty	11.5	75-90	<2
Adult female	12.0	80-95	<2
Adult male	14.0	80-95	<2

Hb, hemoglobin.

TABLE 22.2 CONDITIONS ASSOCIATED WITH DISCORDANCE BETWEEN HEMOGLOBIN CONCENTRATION AND RED CELL MASS

Increase in plasma volume relative to RBC mass (Hb disproportionately low)

Hydremia of pregnancy

Congestive splenomegaly

Recumbency (vs. upright)

Decrease in plasma volume relative to RBC mass (Hb high, normal, or low; but high relative to RBC mass)

Dehydration

Protracted diarrhea (especially in infants)

Peritoneal dialysis with hypertonic solutions

Diabetic acidosis

Diabetes insipidus with restricted fluid intake

Burn patients

Stress erythrocytosis, spurious polycythemia

Decrease in plasma volume and RBC mass (Hb normal, RBC mass low)

Acute blood loss

Chronic disease

Hb, hemoglobin; RBC, red blood cell.

- Some abnormal Hb variants have an altered ability to bind and release oxygen, and this can be associated with changes in Hb concentration. For example, Hb Yakima has increased oxygen affinity with a low P50, and higher than normal Hgb levels are characteristic. Conversely, Hb Kansas has decreased oxygen affinity, high P50, and lower than normal Hgb levels. Despite the disparate Hb levels in these cases, both satisfy the criteria of appropriate oxygen delivery for tissue oxygen needs.
- Acute blood loss is another example of the problem of denoting anemia by the Hb concentration or Hct. Immediately after loss of a liter of blood, the Hb concentration/Hct is normal, because the initial response to acute hemorrhage is vasoconstriction. The shift of fluid from extravascular to intravascular space, and thus the decrease in Hb concentration, does not begin for 6 hours, and can continue for 48 to 72 hours. Reticulocytosis occurs after 24 to 48 hours.
- Impaired partial synthesis of one globin chain, as in thalassemia trait, may be reflected in a low Hb (10 g/dl) and a high RBC count (6.5 million/ μ l), thus giving anemia by one measure (Hb) and erythrocytosis by another (RBC). This is largely why the RBC count is the least reliable and least commonly used indicator of anemia.

In addition to the issues listed above, changes in posture also have effects on red cell concentration that can influence Hb and Hct measurements. When normal individuals assume a recumbent position, the Hct falls an average 7% (range, 4% to 10%) within 1 hour.²⁸ When the upright position is resumed, the Hct increases by a similar amount within 15 minutes. These changes have been attributed to alterations in plasma volume as fluid moves between the circulation and the extravascular spaces in the lower limbs as a result of hydrostatic forces.

CLINICAL EFFECTS OF ANEMIA

Patients with anemia usually seek medical attention because of decreased work or exercise tolerance, shortness of breath, palpitations, or other signs of cardiorespiratory adjustments to anemia. At times, they feel fine, but their friends or family may note pallor. It is not uncommon that anemia in a child is first recognized by a visiting relative, the process sometimes occurring so slowly as to not be noted by parents or other immediate family members.

Cardiovascular and Pulmonary Features of Anemia

The clinical manifestations of anemia depend on the magnitude and rate of reduction in the oxygen carrying capacity of the blood, the capacity of the cardiovascular and pulmonary systems to compensate for the anemia, and the associated features of the underlying disorder that resulted in the development of anemia. The Hb concentration is not the only determinant of the observed symptoms. Coexistent cardiovascular or pulmonary disease, particularly in older individuals, may exaggerate the symptoms associated with a degree of anemia that would be well tolerated under other circumstances.

If the anemia has been insidious in onset and there is no cardiopulmonary disease, the patient's adjustment may be so effective that the blood Hb concentration may fall to 8 g/dl or even lower before the patient experiences enough symptoms to appreciate the situation.²⁹ In cases of iron deficiency anemia, pernicious anemia, or other types of slowly developing anemia, Hb concentrations may reach levels of 6 g/dl or lower before patients are motivated to seek medical attention.³⁰ This is particularly true in children where no limitations of physical activity may be apparent despite the existence of very severe anemia.³¹ The physiologic adjustments that take place with a slowly falling red cell mass chiefly involve the cardiovascular system and changes in the Hb-oxygen dissociation curve.

In many patients, respiratory and circulatory symptoms are noticeable only after exertion; however, when anemia is sufficiently severe, dyspnea and awareness of vigorous or rapid heart action may be noted even at rest. When anemia develops rapidly, shortness of breath, tachycardia, dizziness or faintness (particularly upon arising from a sitting or recumbent posture), and extreme fatigue are prominent. In chronic anemia, only moderate dyspnea or palpitation may occur, but in some patients, congestive heart failure,³² angina pectoris, or intermittent claudication³³ can be the presenting manifestation. In patients with severe chronic anemia, tachycardia and postural hypotension may not be present because the total blood volume actually may be increased because of an expanded plasma volume. In the elderly particularly, cardiovascular adaptation to anemia is predominantly by increasing stroke volume, rather than by heart rate.³⁴ It is in these cases that rapid administration of a blood transfusion may precipitate congestive heart failure by aggravating an already expanded blood volume. Concern about this possibility should not preclude expansion of the blood's oxygen carrying capacity by transfusion if necessary; rather the judicious use of diuretics in the peritransfusion period should be considered in patients with clinical signs of volume overload.

Heart murmurs are a common cardiac sign associated with anemia. They usually are systolic in time and best heard in the pulmonic area.^{35,36,37} Often, they are moderate in intensity, and at times may be rough in quality and raise suspicion of organic valvular heart disease. In a study from Bosnia, 25% of the heart murmurs investigated in a pediatric cardiology clinic were attributable to anemia and resolved with its correction.³⁸

P.590

Pallor

Pallor is a sign of anemia, but many factors other than Hb concentration affect skin color. These include the degree of dilation of peripheral vessels, the degree of pigmentation, and the fluid content of the subcutaneous tissues. Certain people routinely have pale-appearing skin without being anemic. Patients with myxedema may manifest pallor without anemia. In simple vasovagal syncope, pallor results from cutaneous vasoconstriction and is not a sign of anemia. Jaundice, cyanosis, racial skin pigmentation, and dilation of the peripheral vessels all can mask the pallor of anemia.

The pallor associated with anemia is best detected in the mucous membranes of the mouth and pharynx, the conjunctivae, the lips, and the nail beds. In the hands, the skin of the palms first becomes pale, but the creases may retain their usual pink color until the Hb concentration is less than 7 g/dl.

A distinctly sallow color implies chronic anemia. A lemonyellow pallor suggests pernicious anemia, but it is observed only when the condition is well advanced. Definite pallor associated with mild scleral and cutaneous icterus suggests hemolytic anemia. Marked pallor associated with petechiae or ecchymoses suggests more generalized bone marrow failure due to acute leukemia, aplasia, or myelodysplastic syndromes.

Skin and Mucosal Changes

Other changes in the integument occur with anemia. Thinning, loss of luster, and early graying of the hair may occur, the last especially in patients with pernicious anemia, in whom it may precede the development of anemia. The nails may lose their luster, become brittle, and break easily. This finding is especially noticeable in chronic iron deficiency anemia,³⁹ in which the nails may actually become concave instead of convex. Chronic leg ulcers may occur, especially in patients with sickle cell anemia and rarely in those with other hemolytic anemias. Glossitis occurs in association with pernicious anemia.

When nutritional deficiency is associated with anemia, symmetric dermatitis may develop, fissures may be present at the angles of the mouth, glossitis may occur, and erythematous lesions on the face, neck, hands, or elbows may be found.

Neuromuscular Features

Headache, vertigo, tinnitus, faintness, scotomata, lack of mental concentration, drowsiness, restlessness, and muscular weakness are common symptoms of severe anemia. Paresthesias are common in pernicious anemia and may be associated with other symptoms and signs of peripheral neuropathy, and more especially with combined system disease.

Ophthalmologic Findings

A variety of ophthalmologic findings have been observed in anemic patients.^{40,41,42} Approximately 20% of such patients have flame-shaped hemorrhages, hard exudates, cottonwood spots, or venous tortuosity affecting the retina. The hemorrhages occur even in the absence of coexisting thrombocytopenia. Papilledema related solely to anemia has been described,^{43,44} and it clears when the anemia disappears.

Gastrointestinal Changes

Gastrointestinal symptoms are common in anemic patients. Some are manifestations of the underlying disorder (e.g., hiatal hernia, duodenal ulcer, or gastric carcinoma); others may be a consequence of the anemic condition, whatever its cause. Glossitis and atrophy of the papillae of the tongue commonly occur in pernicious anemia and less often in iron deficiency anemia. Painful, ulcerative, and necrotic lesions in the mouth and pharynx occur in aplastic anemia and in acute leukemia, usually reflecting the neutropenia accompanying these conditions. Dysphagia may occur in chronic iron deficiency anemia.

EVALUATION AND CLASSIFICATION OF ANEMIA

History and Physical Examination

All aspects of the history and clinical examination are important. The duration of the symptoms and their onset, whether insidious or acute, should be established. It is very helpful to know the most recent date at which a routine hematologic examination was normal.

The family history is most useful for increasing suspicion of hereditary hemolytic diseases (including hemoglobinopathies) and hereditary bleeding disorders (including hereditary vascular abnormalities like hereditary hemorrhagic telangiectasias). Key clues are histories of bleeding, jaundice, gallstones, and splenectomy (see Approach to Hemolysis).

The patient's occupation, household customs, and hobbies must be ascertained because certain drugs, solvents, and other chemicals may produce hemolytic anemia or aplastic anemia, as well as granulocytopenia and thrombocytopenia. Also, social habits (alcohol use), travel history (to malarious or other infectious areas), and drug history are all important in ascertaining the underlying etiology.

The dietary history is critical to the analysis, and questions regarding the diet must be specific in the hope of obtaining quantitative information. In very young children, those who obtain the bulk of their nutrition from cow's milk (good for calories, very low in iron) are at great risk for iron deficiency anemia. Changes in weight are most important in both adults and children. Formerly obese individuals who have undergone bariatric surgery and other individuals who have undergone gastric resection are at risk for anemia from iron, copper, and other nutrient deficiencies.⁴⁵

The patient should be questioned about early graying of the hair, burning sensations of the tongue, skin changes, sores about the angles of the mouth, and discomfort and brittleness of the fingernails, which are symptoms of anemias caused by deficiency of specific nutrients.

Change in stool habits may be an important clue to neoplasms of the colon and rectum underlying the anemia. The significance of tarry stools often is not appreciated by patients, and specific inquiry is necessary. The amount of blood lost from hemorrhoids may be overlooked or overestimated. In men, occult blood loss most often is from the gastrointestinal tract.

In women, additional important information includes an appraisal of the amount of blood lost during menstruation. Data about number of pads or tampons used and the presence or absence of clots should be obtained. The average amount of blood lost per period is approximately 50 ml, representing roughly 25 mg of elemental iron. Menstrual flow should be deemed excessive if more than 12 pads are used each period, if clots are passed after the first day, or if the period duration exceeds 7 days. The number of pregnancies and abortions and the interval since the most recent of these are also important, for each represents significant iron loss.

The presence or absence of fever must be known; its presence suggests infection, lymphoma, other neoplasm, or collagen vascular disease. Pains in the limbs, paresthesias, and difficulty in walking suggest pernicious anemia. Abnormal color of the urine, suggesting blood or Hb, may signify urinary tract disease or hematologic problems. Bilirubin is not detected in the urine of people with uncomplicated hemolytic anemia (“acholuric

P.591

jaundice”), but a darker than normal color may result from the increased excretion of urobilinogen and its conversion to urobilin.

Bruises, ecchymoses, and petechiae are other important points in the history. Their presence indicates that the disorder producing anemia may also involve platelets or the liver. Alternatively, the anemia itself may be the consequence of blood loss resulting from a disorder of hemostasis.

In all instances, the presence or absence of symptoms suggestive of an underlying disease such as chronic renal disease, liver disease, chronic infection, endocrinopathy, or malignancy must be explored. Anemia can be the presenting feature of many of these disorders.

The physical examination can provide further clues to the cause of anemia. Scleral icterus suggests the presence of hemolytic anemia or ineffective erythropoiesis. Sternal tenderness near the middle or lower third of the sternum, of which the patient may have been unaware, may represent acute expansion of hematopoietic marrow and can be a useful sign in some patients with acute leukemia. Palpation of the liver and spleen and a systemic check for lymphadenopathy can provide clues to infection, lymphoma, leukemia, or metastatic carcinoma.

The initial patient evaluation should include a urinalysis. Even when the color of the urine does not suggest blood, the routine urinalysis should be tested for occult blood. A positive reaction may be due to hematuria, hemoglobinuria, or even myoglobinuria. Hematuria may be differentiated from the other conditions by finding RBCs on microscopic examination of the urine, or by centrifuging a fresh urine specimen, thereby clearing the bloody color from the supernatant and depositing the RBCs in the bottom of the tube. Hematuria reflects disease of the kidneys or urinary tract. Sickle cell trait may be accompanied by innocuous hematuria. Hemoglobinuria implies intravascular hemolysis. The significance of urobilinogen has been noted above.

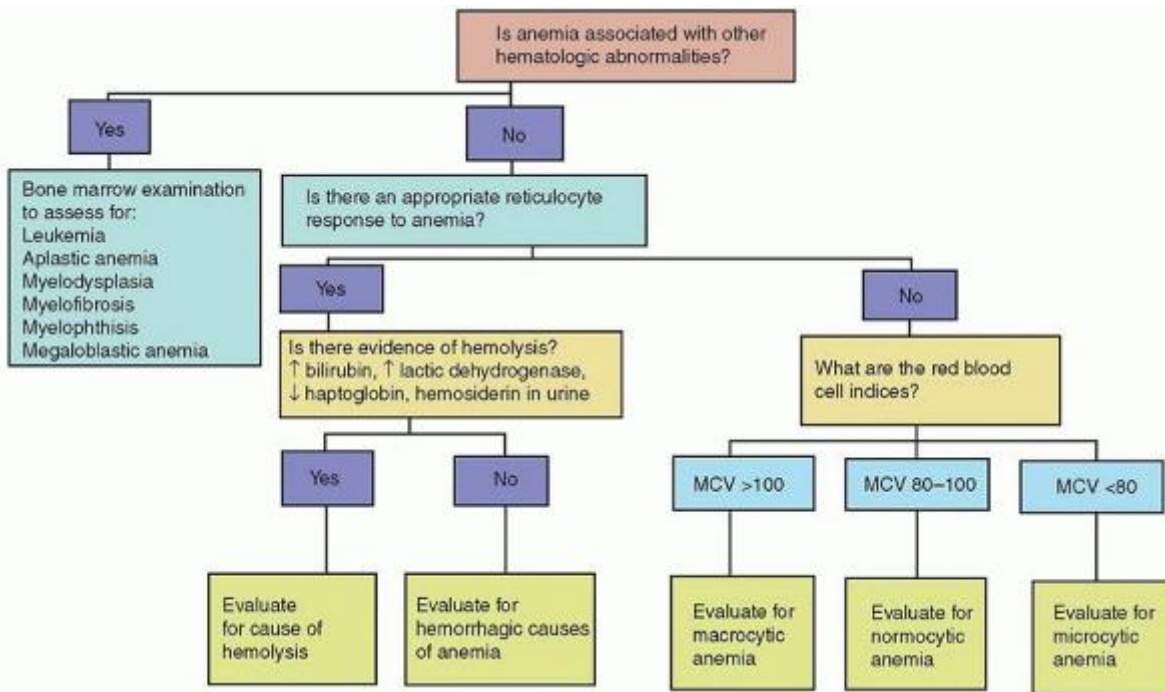

FIGURE 22.2. Questions to ask in the initial evaluation of anemia. MCV, mean corpuscular volume (fl); ↑, increased; ↓, decreased.

Evaluation of Basic Hematology Laboratory Data

To identify the cause of anemia, information from the medical history and physical examination must be integrated with some key laboratory tests. There is no one simple classification of anemia. A useful approach entails asking several questions, outlined in the following sections (Fig. 22.2).

Is Anemia Associated with Other Hematologic Abnormalities?

Specifically, is the anemia associated with thrombocytopenia or abnormalities in white blood cell numbers or the presence of abnormal leukocytes? If the answer to this question is yes, consideration must be given to the possibility of bone marrow failure due to aplastic anemia, leukemia, or other malignant marrow disease. Alternatively, pancytopenia can be secondary to peripheral destruction or sequestration of cells as in hypersplenism. In most cases, these disorders can be differentiated by careful review of screening hematologic studies and close attention to the medical history and physical examination.

Is There an Appropriate Reticulocyte Response to Anemia?

The number of erythrocytes in the circulation at a given time is the result of a dynamic equilibrium between the delivery of red cells into the circulation on the one hand and their destruction or loss from the circulation on the other. Each day, approximately 1% of the RBC pool is replaced by young erythrocytes released from the marrow. The homeostatic mechanisms of the body bring about recovery from anemia by accelerating erythropoiesis, and this response of the normal marrow is brought about through

P.592

the release of erythropoietin. At maximum stimulation, the bone marrow is capable of producing erythrocytes at six to eight times the normal rate.

The reticulocyte count provides an initial assessment of whether the cause of anemia is due to impaired RBC production or to increased loss in the peripheral circulation (e.g., blood loss, hemolysis) (Fig. 22.2). The reticulocyte count is traditionally measured by microscopic examination of a smear prepared from fresh blood stained with a supravital stain, such as new methylene blue. The normal reticulocyte count by light microscopy is 0.5% to 1.5% of the total red cells. More recently, automated methods based on flow cytometry have become widely utilized. The automated methods count a larger number of cells, and exhibit a greater degree of reproducibility.⁴⁶

In the presence of anemia, the reticulocyte count must be corrected because it is spuriously elevated when it is related to the reduced number of RBC in an anemic patient. An additional correction of this index needs to be made because reticulocytes released under intense erythropoietin stimulation remain in the peripheral blood for more than the usual 1-day survival time of nonstress reticulocytes. There are a number of ways to adjust the reticulocyte count for the degree of anemia (Table 22.3). While all of these methods have value, the absolute reticulocyte count is traditionally the easiest to estimate.

Automated reticulocyte counting also allows the evaluation of other parameters, such as reticulocyte hemoglobin content (CHR) and the proportion of immature reticulocytes (immature reticulocyte fraction, IRF). Availability of these methods depends on the particular cell counting equipment. A CHR < 28 pg suggests iron deficiency,⁴⁷ while a reduced IRF (<0.23) suggests underproduction.⁴⁸ The degree to which the IRF adds to information provided by any of the adjusted reticulocyte parameters is unclear.

If Anemia Is Associated with Reticulocytosis, Is There Any Evidence for Hemolysis?

The most characteristic presentation of hemolysis is reticulocytosis with some degree of hyperbilirubinemia as a marker of increased heme catabolism. Other markers reflect direct red cell injury (e.g., increased serum lactic dehydrogenase) or increased excretion of Hb (e.g., low serum haptoglobin, hemoglobinemia, hemoglobinuria, and increased urinary hemosiderin). The evaluation and diagnostic considerations related to hemolytic anemia are complex and are considered separately elsewhere in this chapter (see Approach to Hemolysis).

TABLE 22.3 METHODS OF CORRECTING THE RETICULOCYTE COUNT FOR THE DEGREE OF ANEMIA

Reticulocyte count = % reticulocytes in red blood cell (RBC) population

Corrected reticulocyte count = % reticulocytes × (patient Hct/45)

Reticulocyte production index

= Corrected reticulocyte count ÷ maturation time in peripheral blood in days^a (Normal values of all of

above 0.5-1.5%)

Absolute reticulocyte count = % reticulocytes \times RBC count/L³

(Normal values for the absolute reticulocyte count are from 25 to 75 $\times 10^9$ /L; values $< 100 \times 10^9$ /L indicate an inappropriately low erythropoietic response to anemia.)

^a Reticulocyte maturation time = 1 day for Hct $\geq 40\%$; 1.5 days for Hct 30-40%; 2.0 days for Hct 20-30%; 2.5 days for Hct $< 20\%$.

Data from Hillman RS, Finch CA. Red cell manual, 5th ed. Philadelphia, PA: FA Davis, 1985.

If Anemia Is Associated with a Less Than Appropriate Reticulocyte Response, What Are the Red Cell Indices?

Anemia with low reticulocytes usually reflects some impairment of normal erythropoiesis, and this can be due to two kinds of defects. Erythropoiesis may be impaired because of a reduction in red cell precursors (hypogenerative). Alternatively, red cell production may be ineffective, a condition characterized by erythroid hyperplasia in the bone marrow, but with the production of essentially nonviable red cells, most of which do not reach circulation.

There are numerous causes of anemia with low reticulocyte counts, and it is in this group that analysis of RBC indices is most helpful. Of these, the MCV tends to be the single most useful measurement,^{49,50,51} although some clinicians prefer to use the MCH.⁵² The MCV and MCH almost always correlate closely.^{53,54}

An initial step in classification of anemias with low reticulocyte counts separates them into three groups on the basis of average cell size: the macrocytic, microcytic, and normocytic anemias (Fig. 22.2). Anemia is classified as macrocytic if MCV exceeds 100 fl. Usually, the MCH is also increased, whereas the MCHC remains within normal limits (Fig. 22.3). Microcytic anemia is identified when the MCV is less than 80 fl in adults. The anemia is normocytic when the indices are within normal limits, with an MCV between 80 and 100 fl. In children, MCV values vary as a function of age, and, correspondingly, the definition of microcytic, normocytic, and macrocytic differ accordingly (Table 22.1). As a practical matter for those who take care of children, it is important to know the age-related differences in RBC size, because many laboratory reports contain only adult normal values, often signaling the child's age appropriate hematologic values as abnormal.

The MCHC is useful in detecting severe hypochromia, but it is rarely abnormal when the MCV is normal.^{51,52,53,54,55,56} A reduced value for MCHC is observed most often in association with iron deficiency, and this index tends to be the last to fall as iron deficiency worsens.^{57,58,59} The changes in MCHC with iron deficiency were seen more frequently in the past when centrifugal methods were used to determine the Hct before the availability of electronic cell counting. Because of plasma trapping, centrifugal Hct methods overestimate the volume of packed red cells and, therefore,

P.593

underestimate MCHC. Plasma trapping increases from 1% to 3% with normal blood to as much as 6% in iron deficiency, a consequence of anisocytosis and reduced cell deformability.⁶⁰

FIGURE 22.3. Erythrocyte indices in 28 patients with untreated or relapsed pernicious anemia. Dashed lines enclose the 95% confidence limits in normal subjects. Solid dots indicate males; open circles indicate females. MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume. (From Hallberg L. Blood volume, hemolysis and regeneration of blood in pernicious anemia. *Scand J Clin Lab Invest* 1955;7(Suppl 16):1-127, with permission.)

Is the Anemia Associated with a Low Reticulocyte Response and Microcytic Red Blood Cells?

The large majority of patients in this category have defects in cellular Hb synthesis due to either iron deficiency, thalassemia trait, or Hb E syndromes (see Approach to Microcytic Anemia).

Is the Anemia Associated with a Low Reticulocyte Response and Macrocytic Red Blood Cells?

In these patients, the anemia is characterized by reticulocytopenia with red cells having an increased MCV. Many of these disorders are due to megaloblastic anemia resulting in impaired nuclear development, and the formation of other blood cells is also affected (see Approach to Macrocytic Anemia).

Is the Anemia Associated with a Low Reticulocyte Response and Normocytic Red Blood Cells?

Normocytic anemia, low reticulocyte count, and normal bilirubin levels characterize a large number of anemias. The anemia of chronic disease usually is normocytic, although rarely may be slightly microcytic. In these cases, there usually is clinical evidence of a syndrome associated with cytokine activation. The anemia of renal failure is normocytic and largely is due to reduced erythropoietin production. Acquired pure red cell aplasia (PRCA) is a normocytic anemia, which occurs in adults and children (see Approach to Normocytic Anemia).

Is the Anemia Associated with Populations of Red Cells of Different Size?

The red cell indices represent mean values and do not reveal any variation that may exist within a population of cells. The MCV can be normal if there are combined abnormalities, such as when iron deficiency (decreased MCV) is accompanied by a megaloblastic anemia (increased MCV). For these purposes, it is important to examine the peripheral blood smear. Also, the electronically derived RDW allows for recognition of these phenomena because it quantifies the degree of heterogeneity of RBC size (i.e., anisocytosis) in a population of cells, and this has proven to be of value.^{49,61} The upper limit of normal values for RDW is 14.6%.⁴³ An increased RDW value is an early and pronounced finding in iron deficiency and most megaloblastic anemias; no differences from normal are seen in heterozygous thalassemia. In iron deficiency, the RDW value may become abnormal even before the MCV falls below the lower limits of normal.

Is the Anemia Associated with Abnormalities Seen on the Blood Smear?

Despite the technical advances provided by current electronic complete blood cell count (CBC) measurements, review of the peripheral blood smear remains a critical aspect of the diagnostic evaluation for anemia. It confirms the electronically determined classification of RBC size. Most important, it also allows for recognition of the many variations in RBC size and shape that frequently are seen in patients with hemolysis.

Microcytes and macrocytes can be detected on the blood smear on the basis of a change in red cell diameter. Normal red cells approximate the size of the nucleus of a small lymphocyte, and the area of central pallor is one-third to one-half of the diameter of the red cell (Fig. 22.4A). An increase in the area of central pallor of erythrocytes on the blood smear is indicative of hypochromia, and when the change is pronounced, little more than a faint ring of color in the periphery may be apparent (Fig. 22.4B). Hypochromia and microcytosis almost always occur together.

The automated analysis of the blood has made the erythrocyte indices more accurate and reproducible.⁶² However, the evaluation of the blood smear still remains important because it may reveal abnormal cell populations too small to affect the erythrocyte indices. For example, as iron deficiency develops, some microcytic cells are produced while the RBC indices are still normal. Furthermore, as B12 deficiency progresses, some characteristic oval macrocytes and hypersegmented neutrophils may appear long before there are MCV or Hb changes (Fig. 22.5B,C). Moreover, examination of the smear is important for detecting conditions characterized by two populations of cells, only one of which is of abnormal size. This dimorphic anemia is particularly characteristic of sideroblastic anemias (Fig. 22.4E). It also is seen in iron deficiency after iron therapy is started (Fig. 22.4C), and in iron deficient individuals who have been transfused.

Review of the blood smear may reveal underlying causes of the anemia. A leukoerythroblastic picture (teardrop RBC, nucleated RBC, early white blood cell precursors, or abnormalities in platelet shape) suggests marrow infiltration by hematologic or other malignant cells (Fig. 22.6). The marked elevation in serum proteins in multiple myeloma may result in a stacking of RBCs in rouleaux formation. The appearance of RBC in agglutinates (as opposed to their stacking into rouleaux) is seen with cold agglutinin disease. Also, probably one of the most valuable outcomes of reviewing the blood smear is that it often reveals abnormal red cell shapes characteristic of certain hemolytic anemias in particular.

Is a Bone Marrow Examination Needed to Clarify the Cause of Anemia?

Examination of the bone marrow is most useful in reticulocytopenic anemias, particularly when there is more than one hematopoietic cell line affected. Both hypoplasia and marrow infiltrative disease due to leukemia, tumor, or granulomas (myelophthitic anemia) may readily be demonstrated in the bone marrow aspirate and biopsy. Myelofibrosis can be recognized as a component of myeloid metaplasia. If the marrow is normocellular except for reduced erythropoiesis, the underlying cause may be red cell aplasia, renal disease, or endocrinopathy.

Examination of iron in bone marrow macrophages was traditionally considered the definitive way to demonstrate decreased iron stores. In most cases, however, the diagnosis of iron deficiency can be made by simple blood tests, thus obviating the need for an iron stain of the bone marrow. On the other hand, to make the diagnosis of sideroblastic anemia, a bone marrow examination is necessary to identify ringed sideroblasts. Megaloblastic anemias usually can be recognized by peripheral blood findings, but a marrow examination will confirm the diagnosis.

In some anemias with low reticulocyte counts, marrow erythropoiesis surprisingly is quite active. This is referred to as ineffective erythropoiesis, and it occurs when developing red cells are defective and are destroyed before they leave the marrow or shortly thereafter. A very small fraction of erythropoiesis is ineffective, even in normal subjects; however, in certain conditions, especially megaloblastic anemias, thalassemias, sideroblastic anemias, and congenital dyserythropoietic anemias, ineffective erythropoiesis becomes greatly exaggerated. The increased intramedullary destruction of erythroblasts in these conditions is associated with accelerated heme catabolism, resulting in an elevated unconjugated bilirubin level in the plasma. Also, the serum lactic dehydrogenase level, a marker of cell destruction, is

markedly elevated. Ineffective erythropoiesis can be confused with hemolytic anemia because signs of excessive red cell destruction and

P.594

erythroid hyperplasia of the bone marrow are found in both conditions. However, the two conditions are distinguished from one another by the degree of reticulocytosis, which is increased in hemolytic anemia and usually low in ineffective erythropoiesis.

FIGURE 22.4. Peripheral blood smear of erythrocytes in a variety of hypochromic, microcytic anemia. A: Normal red cells. B: Iron deficiency anemia. Note the large area of central pallor. C: Dimorphic population of cells in iron deficiency anemia responding to treatment. D: Thalassemia minor. The cells are thin and appear pale but nearly normal in diameter. Note the basophilic stippling in several RBC: Sideroblastic anemia. A hypochromic, microcytic population of cells is mixed with relatively normocytic red blood cell. Part C from Tkachuk DC, Hirschmann JV] in Wintrobe's atlas of clinical hematology.

Philadelphia, PA: Lippincott Williams & Wilkins, 2012 and Tkachuk DC, Hirschmann JV in Wintrobe's atlas of clinical hematology. Philadelphia, PA: Lippincott Williams & Wilkins, 2007.

APPROACH TO MACROCYTIC ANEMIA

Macrocytosis is a common finding in clinical settings. In 1.7% to 3.6% of cases involving patients seeking medical care, MCV is increased, often in the absence of anemia.^{63,64,65,66,67,68} Mild macrocytosis (MCV of 100 to 110 fl) is particularly common and often remains unexplained, even after careful study.⁶³ Even so, this finding should not be ignored, because it can be an important early clue to reversible disease. For example, it may appear 1 year or more before anemia develops in patients with pernicious anemia, and neurologic disease can progress during that interval.⁶⁹

Morphologic and biochemical criteria allow macrocytic anemias to be divided into two groups: the megaloblastic anemias and the nonmegaloblastic macrocytic anemias. The types of macrocytic anemias clinicians encounter vary considerably depending on the population served. If alcoholism is common in the

P.595

population, it is likely to be the most common cause. In cancer patients, high MCVs are most likely due to chemotherapy. In hospitals largely serving the elderly, pernicious anemia and other nutritional anemias may predominate.⁶⁸

FIGURE 22.5. Megaloblastic anemia. A: Normal red cells. B: Macroovalocytes in pernicious anemia. From Pierira I, George TI, Arber DA in Atlas of peripheral blood. Philadelphia, PA: Lippincott Williams & Wilkins, 2012. C: Hypersegmented neutrophils seen in patient with megaloblastic anemia.

When confronted with a diagnostic problem involving macrocytic anemia, the physician should first distinguish between megaloblastic and nonmegaloblastic anemia (Fig. 22.7). The most useful steps for this purpose are morphologic examinations.

FIGURE 22.6. Peripheral blood smear. A leukoerythroblastic response seen in patient with metastatic breast cancer. From Pierira I, George TI, Arber DA in Atlas of peripheral blood. Philadelphia, PA: Lippincott Williams & Wilkins, 2012.

Megaloblastic Anemias

The term megaloblast is a designation that was first applied by Ehrlich to the abnormal erythrocyte precursors found in the bone marrow of patients with pernicious anemia. Megaloblasts are characterized by their large size and by specific alterations in the appearance of their nuclear chromatin (Fig. 22.8). These distinctive cells are now known to be the morphologic expression of a biochemical abnormality: retarded DNA synthesis.⁷⁰ RNA synthesis remains unimpaired while cell division is restricted.^{71,72} As a result, cytoplasmic components, especially Hb, are synthesized in excessive amounts during the delay between cell divisions. An enlarged cell is the product of such a process. Megaloblastic anemias are defined by the presence of these cells or by other evidence of defective DNA synthesis.

A pathogenetic classification of the causes of megaloblastic anemias is presented in Table 22.4. Most often, megaloblastic anemia is the consequence of deficiency of vitamin B₁₂ or folate, or both. Less commonly, megaloblastic anemia results from inherited or drug-induced disorders of DNA synthesis.

Hematologic Features of Megaloblastic Anemia

Examination of the blood smear often reveals the two most valuable findings for differentiating megaloblastic from nonmegaloblastic anemia: neutrophil hypersegmentation and oval macrocytes.

Neutrophil hypersegmentation is one of the most sensitive and specific signs of megaloblastic anemia (Fig. 22.5C). Normally, the nuclei of circulating, segmented neutrophils have fewer than five

P.596

lobes. In megaloblastic anemia, neutrophils with six or more lobes may be detected. In a large study, more than 98% of patients with megaloblastic anemia had at least one six-lobed neutrophil of the 100 cells examined, as compared with only 2% of normal control subjects.⁷³ Hypersegmentation is among the first hematologic abnormalities to appear as the megaloblastic state develops.⁷⁴ It persists for an average of 14 days after institution of specific therapy.⁷⁵

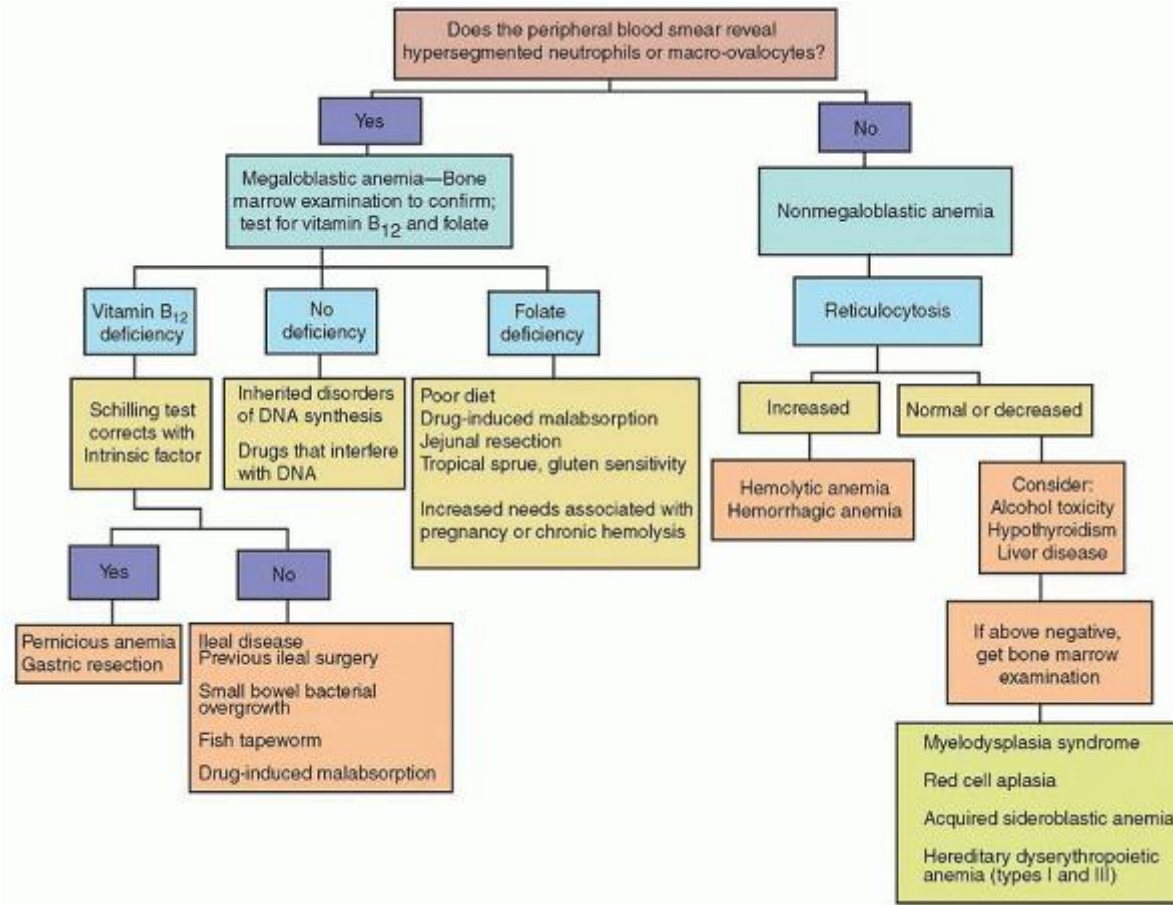

FIGURE 22.7. Diagnostic approach to a patient with macrocytic anemia.

The main products of megaloblastic erythropoiesis are macrocytic erythrocytes with a distinctly oval shape. Such cells are well filled with Hb, and often central pallor is reduced or absent (Fig. 22.5B). The oval shape may be useful in distinguishing megaloblastic anemias from other causes of macrocytosis; the macroreticulocytes that characterize accelerated erythropoiesis tend to be round and distinctly blue or gray in Romanowsky dyes.

Although oval macrocytes are prominent in megaloblastic anemia, the size and shape of the erythrocytes may vary considerably. Quantitative measures of anisocytosis, such as the RDW, are substantially increased, and the increase may precede the development of anemia.⁷⁶ Morphologic changes on the blood smear, however, are most conspicuous when anemia is pronounced.

Megaloblastic anemias usually develop gradually, and the degree of anemia is often severe when first detected. Hb values less than 7 or 8 g/dl are not unusual. Macrocytosis characteristically precedes the development of anemia^{69,77,78} and may even do so by several years. The MCV usually is between 110 and 130 fl.

Bone Marrow

A megaloblastic marrow is cellular and usually hyperplastic, with erythrocyte precursors predominating. The characteristic megaloblasts are distinguished by their large size and especially by their delicate nuclear chromatin. The chromatin has been described as particulate or sieve-like, as distinguished from the normal denser chromatin of normoblasts (Fig. 22.8). This morphologic change may be detected at all stages of erythrocyte development; however, the identification of orthochromatic megaloblasts is particularly useful in the recognition of megaloblastic anemia because they differ so markedly from any cell found in normal marrow. In the orthochromatic megaloblast, the abundant cytoplasm appears mature (pink), whereas the nucleus appears immature as a result of the megaloblastic change.

Leukopoiesis is also abnormal; extraordinarily large (up to 20 or 30 μm) leukocytes are found. These abnormalities of cellular development may occur at any stage in the myeloid series, but they are particularly common among the metamyelocytes. The nucleus of these giant metamyelocytes is enlarged, both absolutely and in relation to the total cell size; it may be bizarre in shape and in chromatin structure or staining properties.

In general, megakaryopoiesis is less disturbed than that of either of the other two cell lines; however, when megaloblastic change is severe, megakaryocytes may be reduced in number and abnormalities of nuclear chromatin may be evident.

Vitamin B₁₂ and Folate Levels in Serum and Erythrocytes

Once it is established that a patient has CBC and morphologic evidence of megaloblastic anemia, it should next be determined if this is due to vitamin B₁₂ or folate deficiency (Chapter 36). Useful studies include measurement of serum and RBC folate levels and serum Vitamin B₁₂ levels. Unlike serum vitamin B₁₂, serum folate is labile, being sensitive to short-term changes in folate balance. Thus, serum folate concentration may increase within a few hours after consumption of folate-containing food. Furthermore, a low intake of folate may result in reduced serum levels before true deficiency develops.⁷⁴ The erythrocyte folate level is a much better index of tissue folate stores. Erythrocyte folate levels are established during formation of the red cell and persist throughout its lifespan. Thus, it may take 3 to 4 months of folate deprivation

P.598

before low values are obtained. Other studies such as serum homocysteine and serum methylmalonic acid can confirm a diagnosis of B₁₂ deficiency, particularly when initial assays are at odds with the clinical and hematologic picture. Vitamin B₁₂ absorption studies (Schilling test) or antibodies to intrinsic factor or parietal cells, can further define the specific causes of these disorders.

TABLE 22.4 PATHOGENETIC CLASSIFICATION OF MEGALOBLASTIC ANEMIA

Vitamin B₁₂ deficiency

Dietary deficiency (rare)

Lack of intrinsic factor

Pernicious anemia

Gastric surgery

Ingestion of caustic materials

Biologic competition for vitamin B₁₂:

Small-bowel bacterial overgrowth

Fish tapeworm disease

Familial selective vitamin B₁₂ malabsorption (Imerslund-Gräsbeck syndrome)

Drug-induced vitamin B₁₂ malabsorption

Chronic pancreatic disease

Zollinger-Ellison syndrome

Diseases of the ileum

Previous ileal resection

Regional enteritis

Folate deficiency

Dietary deficiency

Increased requirements:

Pregnancy

Chronic hemolytic anemia

Alcoholism

Congenital folate malabsorption

Drug-induced folate deficiency

Extensive intestinal (jejuna) resection

Combined folate and vitamin B₁₂ deficiency
 Tropical sprue
 Gluten-sensitive enteropathy
 Inherited disorders of DNA synthesis
 Orotic aciduria
 Lesch-Nyhan syndrome
 Thiamine responsive megaloblastic anemia
 Transcobalamin II deficiency
 Homocystinuria and methylmalonic aciduria
 Drug- and toxin-induced disorders of DNA synthesis
 Folate antagonists (e.g., methotrexate)
 Purine antagonists (e.g., 6-mercaptopurine)
 Pyrimidine antagonists (e.g., cytosine arabinoside)
 Alkylating agents (e.g., cyclophosphamide)
 Zidovudine (AZT, Retrovir)
 Trimethoprim
 Oral contraceptives
 Nitrous oxide
 Arsenic
 Nonmegaloblastic Macrocytic Anemias

Nonmegaloblastic anemias are not united by any common pathogenetic mechanism. They simply represent macrocytic anemias in which the RBC precursors appear normal without the characteristic nuclear and cytoplasmic findings of megaloblastosis. When macrocytosis is found, it tends to be mild; the MCV usually ranges from 100 to 110 fl and rarely exceeds 120 fl.⁶⁴ Several causes of nonmegaloblastic macrocytosis are recognized (Table 22.5).

Accelerated Erythropoiesis

Mild to moderate macrocytosis often follows erythropoietin-mediated acceleration of red cell production, as may be induced by blood loss or hemolysis. In part, this increased cell size occurs because reticulocytes are approximately 20% larger than mature red cells.⁷⁹ Also, under conditions of accelerated red cell production, a premature release of bone marrow reticulocytes (shift reticulocytes) occurs, and these cells are even larger and contain more RNA than normal circulating reticulocytes.⁸⁰ Last, an erythroblast cell division may be skipped under this erythropoietic stress, a phenomenon that results in a macroreticulocyte that is approximately twice the normal size.⁸¹

TABLE 22.5 NONMEGALOBLASTIC MACROCYTIC ANEMIAS

Hemolytic anemia/reticulocytosis
 Posthemorrhagic anemia
 Alcoholism
 Liver disease
 Myelodysplastic syndrome
 Myelophthisic anemias
 Aplastic anemia

Acquired sideroblastic anemia

Congenital dyserythropoietic anemia (CDA) types I and III

Diamond-Blackfan anemia

Hypothyroidism

Spurious macrocytosis (paraproteinemia, inflammation)

Alcoholism

Macrocytosis, usually mild, is evident in 40% to 96% of alcoholics, many of whom have no anemia.^{82,83,84} The finding is so characteristic of the condition that testing for macrocytosis has been used as part of the screening procedure for the detection of chronic alcohol use. It may be present in both heavy and moderate drinkers.⁸⁵ Macrocytosis and anemia in alcoholic individuals have several causes. Folate deficiency can lead to megaloblastic anemia, and alcoholic cirrhosis may be associated with spur cell hemolytic anemia. Most often, however, alcoholic macrocytosis is associated with none of these factors and instead results from poorly defined direct effects of alcohol on the bone marrow. Antibodies against acetaldehyde-modified RBC protein are detected in up to 94% of alcoholics with high MCVs, but less frequently in those with normal MCVs.⁸⁵ There are no morphologic stigmata of megaloblastic anemia. Serum and erythrocyte folate levels are usually normal, and the macrocytosis does not respond to folate treatment. If the patient abstains from alcohol use, the MCV returns to normal levels after 2 to 4 months.

Liver Disease

The causes of anemia in liver disease are multifactorial, resulting from intravascular dilution due to hypervolemia, impaired ability of the marrow to respond optimally to the anemia, and in some patients, a severe hemolytic anemia associated with morphologically abnormal erythrocytes (spur cells). The anemia is usually mild to moderate. In cirrhotic patients, the Hb level averages approximately 12 g/dl, and remains above 10 g/dl in the absence of bleeding or severe hemolysis. The anemia of liver disease is mildly macrocytic: the MCV rarely exceeds 115 fl in the absence of megaloblastic changes in the bone marrow. In addition, liver disease is associated with thin macrocytes, defined as cells with increased surface area⁸⁶ but without a corresponding increase in volume.⁸⁷ The increased surface area of thin macrocytes is the consequence of excessive membrane lipids, especially

P.599

cholesterol,⁸⁷ but also phospholipids. On the blood smear, thin macrocytes are characterized by an increased diameter and a visibly enlarged area of central pallor. The characteristic target cell of liver disease is a thin macrocyte. Because the volume of such cells is normal, their presence has no effect on the erythrocyte indices.

Miscellaneous Anemias

Macrocytosis may accompany various anemias with low reticulocyte counts, including myelodysplastic and myelophthistic conditions. The reason for macrocytosis in these disorders is not well understood.

Congenital red cell hypoplasia or Diamond-Blackfan anemia (DBA) is a pure RBC aplasia in children that is due to impaired differentiation of developing erythroblasts (Chapter 39). This disorder is characterized by a life-long anemia that presents in the first few months of life. Many children with DBA have congenital abnormalities, including short stature and skeletal defects (usually affecting the thumb). The diagnosis of DBA is suggested by a macrocytic (although sometimes normocytic) anemia with reticulocytopenia presenting in the first 6 months of life. Bone marrow examination reveals decreased erythroid precursors.

Congenital dyserythropoietic anemias (CDAs) are a group of anemias characterized by ineffective erythropoiesis and dyserythropoiesis (Chapter 40). The term dyserythropoiesis refers to the presence of morphologically abnormal erythroblasts in the bone marrow with multinuclearity, karyorrhexis, or megaloblastic changes. Three major types of CDA have been distinguished on the basis of morphologic and serologic classification, and these have been designated CDA types I, II, and III. The degree of anemia encountered in the CDAs varies considerably. It may range from a mild to moderate anemia that is only discovered or diagnosed later in life to a severe anemia apparent in infancy. Morphologically, the anemia is generally mildly macrocytic in CDA types I and III and is normocytic in CDA type II. In all of the disorders, the bone marrow findings are consistent with ineffective erythropoiesis: there is erythroid hyperplasia along with morphologically abnormal precursors. An elevation in serum lactate dehydrogenase and indirect bilirubin levels may be observed. Decreased serum haptoglobin often is seen.

Spurious macrocytosis can result from laboratory artifacts. Cold agglutinins, marked leukocytosis, or other acute phase reactants can lead to an incorrect high MCV value.⁶⁵ Care is needed so that these situations do not lead to a fruitless search for a disorder known to cause macrocytic anemia. Since reticulocytes are larger than mature RBCs, significant reticulocytosis can increase the MCV. This is not a spurious macrocytosis, but it is misleading.

APPROACH TO MICROCYTIC ANEMIA

Most microcytic anemias are due to deficient Hb synthesis, often associated with iron deficiency or impaired iron use (Table 22.6). The differentiation of iron deficiency from the anemia of chronic disease and the differentiation of iron deficiency from thalassemia trait syndromes are both common clinical issues. Significant microcytosis is detected in nearly 3% of all patients who require admission to the hospital.^{56,88}

The typical Hb level seen in adults with a variety of microcytic anemias is depicted in Table 22.7. The laboratory evaluation of microcytic anemias focuses on screening hematologic studies, followed by more definitive tests to distinguish iron deficiency anemia, the anemia of chronic disease, hemoglobinopathies, or sideroblastic anemias (Fig. 22.9). A few commonly used studies are described below; others are described elsewhere in this text.

Iron Pathway Disorders

The principal source of iron for Hb production is that carried by transferrin, the iron-transport protein in plasma. Under normal circumstances, plasma iron levels are not rate limiting in erythropoiesis, and transferrin is able to supply all the iron required for normal or accelerated production rates. However, in iron deficiency anemia, the storage sites in macrophages are depleted of iron and the plasma iron concentration falls. When transferrin saturation with iron is less than 16%, the red cell production rate decreases, and hypochromic, microcytic cells are manufactured. This state is known as iron deficient erythropoiesis.

TABLE 22.6 PATHOGENIC CLASSIFICATION OF MICROCYTIC ANEMIAS

Disorders of iron metabolism

Iron deficiency anemia

Anemia of chronic disorders

Disorders of globin synthesis

α - and β -thalassemias

Hemoglobin E syndromes (AE, EE, E- β -thalassemia)

Hemoglobin C syndromes (AC, CC)

Sideroblastic anemias

Hereditary sideroblastic anemia

Acquired sideroblastic anemia

Refractory anemia with ringed sideroblasts

Malignancies

Myeloproliferative disorders

Lead intoxication (usually normocytic)

In the anemia associated with chronic disorders (Chapter 41), the macrophage iron level is normal or increased, but export of iron from macrophages is downregulated.⁸⁹ Thus, iron accumulates in the macrophage, whereas the plasma level falls, and the marrow is deprived of adequate supplies.

Together, iron deficiency anemia and the anemia of chronic disease are among the most common causes of anemia. Iron deficiency predominates in children and young women; but it also occurs in older individuals, in whom it may reflect occult bleeding due to underlying pathology. The anemia of chronic disorders is most common among elderly people,⁹⁰ but it also can occur in younger individuals affected by certain chronic inflammatory states.

TABLE 22.7 TYPICAL HEMOGLOBIN AND MEAN ORPUSCULAR VOLUME VALUES IN ADULTS WITH CERTAIN ANEMIAS

Condition	Hb Concentration (g/dl)	MCV (fl)
Normal men	16 (14-18)	89 (80-100)
Normal women	14 (12-16)	89 (80-100)
Iron deficiency anemia	8 (4-12)	74 (55-85)
Anemia of chronic diseases	10 (8-13)	85 (75-95)
β -Thalassemias minor	12 (9-14)	68 (55-75)
β -Thalassemias major	(2-7)	(48-72)
Hemoglobin H disease	9 (7-11)	70 (53-88)
Hemoglobin E trait (AE)	14 (12-17)	73 (71-78)
Homozygous hemoglobin E (EE)	12 (11-15)	64 (58-76)
Hemoglobin C disease (CC)	10 (7-14)	77 (55-93)
Congenital sideroblastic anemia	6 (4-10)	77 (49-104)
Acquired sideroblastic anemia	10 (7-12)	104 (83-118)

Note: Values are means, with approximate range in parentheses. Hb, hemoglobin; MCV, mean corpuscular volume.

P.600

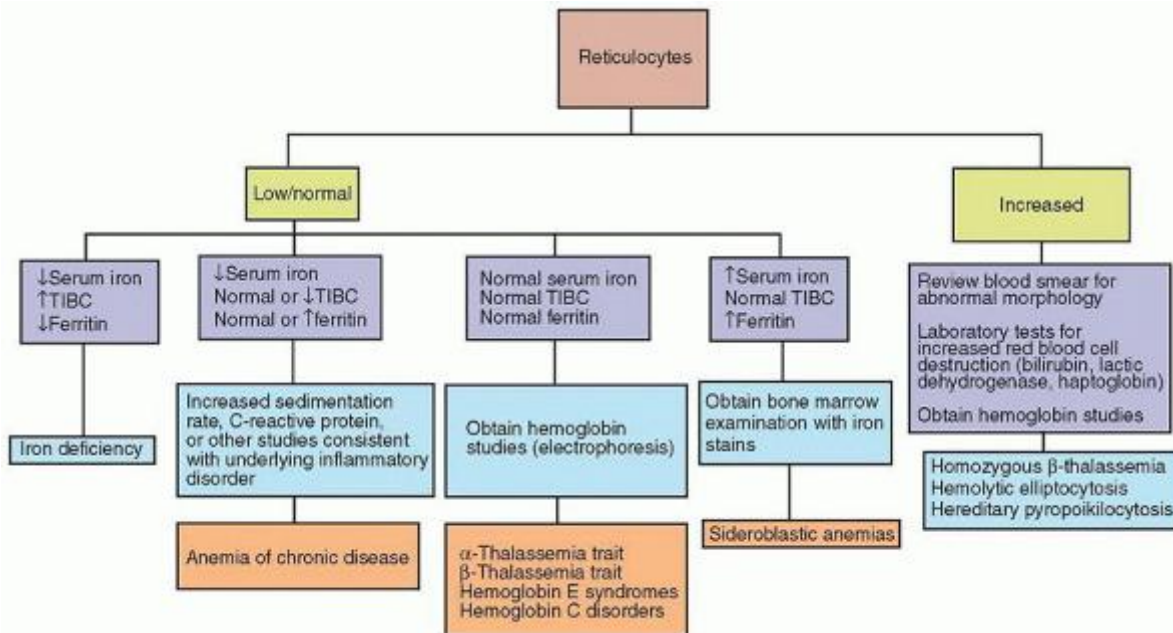

FIGURE 22.9. Diagnostic approach to a patient with microcytic anemia. ↑, increased; ↓, decreased.

Distinguishing typical iron deficiency anemia from the anemia of chronic disorders is usually not difficult. Anemia, hypochromia, and microcytosis are typically more pronounced in iron deficiency, as are the degrees of anisocytosis and poikilocytosis. The anemia of chronic disease is usually normocytic. However, when iron deficiency is early and mild, the morphologic findings in the two conditions may be similar.

Measurement of Serum Iron and Iron-binding Capacity

Serum iron levels are a measure of the amount of iron bound to transferrin. Total iron-binding capacity (TIBC) is an indirect measurement of transferrin in terms of the amount of iron it will bind. Transferrin also can be measured directly by immunologic techniques and is available in many laboratories.

A limitation in the use of serum iron determinations is the considerable variability in values.^{51,62,91,92} A technical problem relates to contamination of glassware and reagents with iron, although the use of disposable, plastic equipment has significantly reduced such contamination as a clinical issue. Even if technical problems are eliminated, serum iron values in an individual can vary from 10% to 40% within a single day or from day to day,^{93,94} and many normal subjects demonstrate a predictable diurnal variation, with highest values in the morning and lowest values in the evening.⁵² In contrast to serum iron, TIBC (or transferrin) values show only slight day-to-day fluctuation or diurnal variation.⁹¹ It also must be recognized that serum iron levels are influenced by the recent ingestion and absorption of iron medication.

The normal mean serum iron value for men is approximately 120 µg/dl (21.8 µmol/L). The composite normal range is approximately 70 to 200 µg/dl (13 to 36 µmol/L); however, values vary substantially from one laboratory to another. The TIBC averages 340 µg/L (61 µmol/L) in both men and women, with a composite normal range of 250 to 435 µg/dl (45 to 78 µmol/L). TIBC saturation is calculated with the following formula: $TIBC\ saturation\ (\%) = (\text{serum iron} \times 100) / TIBC$. The normal value is 20% to 45%. Values below 16% are noted in association with both iron deficiency and the anemia of chronic disorders (Fig. 22.10). The degree of reduction tends to be greater in iron deficiency than in chronic disorders, but considerable overlap exists between these two conditions. In both children and adults, however, a value of less than 5% is almost certainly due to iron deficiency anemia. In sideroblastic anemias, and in transfused thalassemic patients, the TIBC saturation invariably is increased and often approaches 100%. In laboratories that measure transferrin directly, an iron transferrin saturation index is calculated that provides the same information as the TIBC saturation.

The absolute value for TIBC may be helpful in distinguishing between iron deficiency and the anemia of chronic disorders. The TIBC often is increased in iron deficiency and decreased in chronic disease (Fig. 22.11), and some consider it to be the best test to distinguish these two disorders,⁹⁵ although in hospitalized patients elevated TIBC is an insensitive marker of iron deficiency.⁹⁶

Serum Ferritin

Determination of serum ferritin concentration also is used for evaluating iron stores in patients with iron deficiency.⁹⁷

Ferritin

P.601

is chiefly an intracellular iron storage protein, but trace amounts are also secreted into plasma. In most clinical circumstances, the serum ferritin concentration is proportional to total body iron stores. In contrast to serum iron measurements, ferritin values are not influenced by recent iron therapy.⁹⁸

FIGURE 22.10. Transferrin iron saturation in patients with several types of anemia. The values are low (>16%) in iron deficiency anemia and the anemia of chronic disorders, with considerable overlap. Values of less than 5% are found only in iron deficiency. Transferrin saturation is increased in sideroblastic anemia.

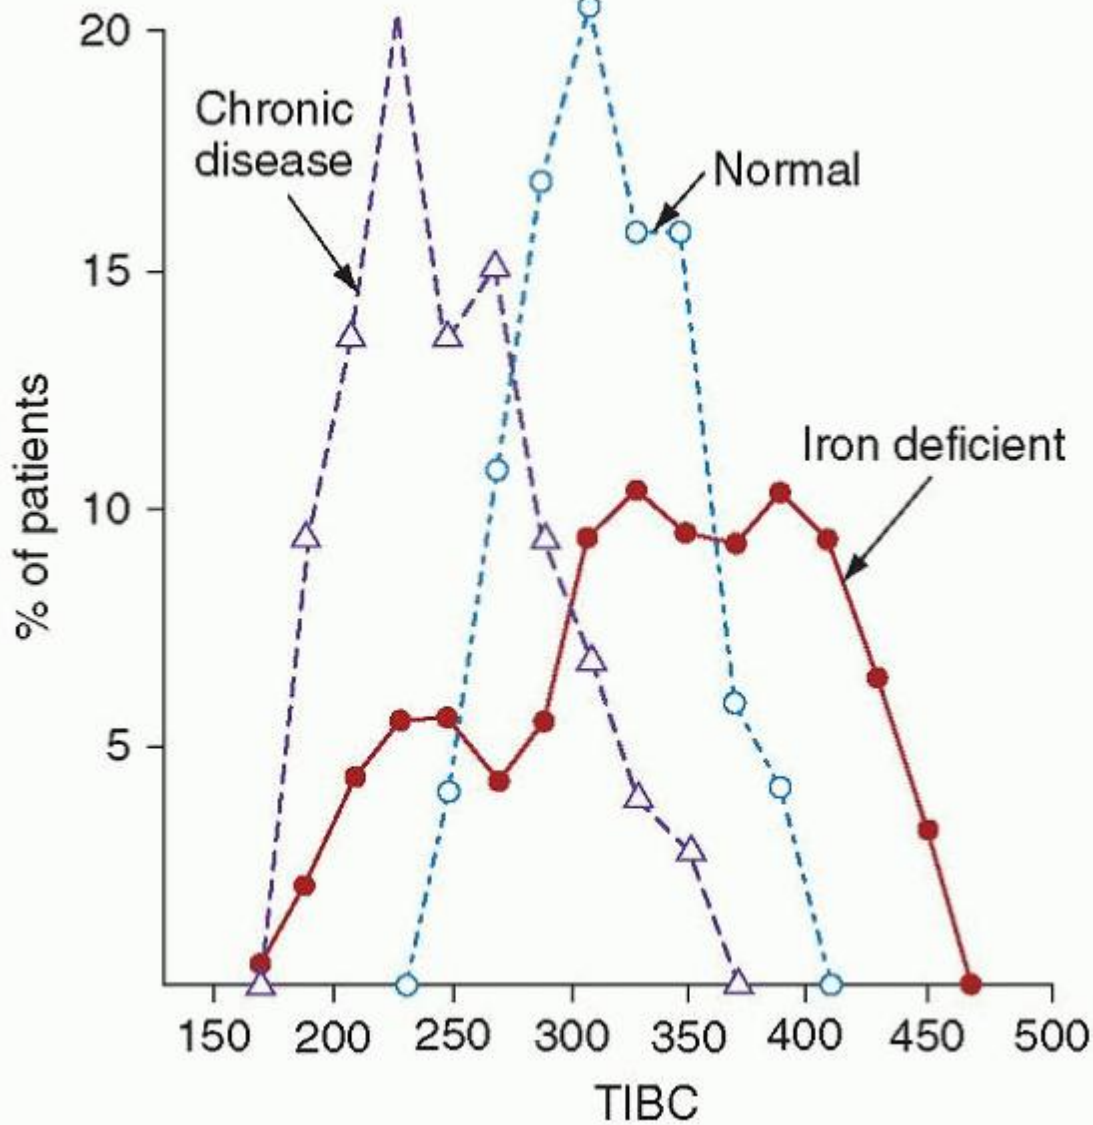

FIGURE 22.11. Total iron-binding capacity (TIBC) in patients with iron deficiency and in those with chronic disease. A high value indicates iron deficiency. Low to normal values are found in chronic disease but may also occur in iron deficiency.

The mean ferritin value for normal adult men is 90 to 95 $\mu\text{g/L}$, with a range of approximately 20 to 500 $\mu\text{g/L}$. For women, mean values of approximately 35 $\mu\text{g/L}$ are noted, with a usual range of 10 to 200 $\mu\text{g/L}$, when iron deficiency anemia is excluded.⁹⁹ In infants, values are high at birth but rapidly fall to approximately 30 $\mu\text{g/L}$, where they remain until puberty. Serum ferritin values in men tend to rise steadily with age. These levels show little or no diurnal variation. Day-to-day variation averages approximately 15%, mostly because of methodologic factors.⁹⁹

In patients with uncomplicated iron deficiency, mean ferritin values of 3 to 6 $\mu\text{g/L}$ have been reported. In patients with excessive iron stores, values are usually greater than 1,000 $\mu\text{g/L}$ and may reach 10,000 $\mu\text{g/L}$ (Fig. 22.12).¹⁰⁰ Also, the serum ferritin level in patients with anemia of chronic diseases may increase disproportionately relative to the increase in iron stores, probably because ferritin is an acute phase reactant. This phenomenon complicates the diagnosis of iron deficiency when it coexists with inflammatory disease. In some other illnesses, the serum ferritin level increases because of factors other than augmented iron stores. One such condition is liver disease, in which damage to the hepatic cell can cause the

release of intracellular ferritin (nonglycosylated and iron-rich).¹⁰⁰ Serum ferritin values also may be inappropriately increased in association with various malignancies, especially hematologic malignancies.^{99,101,102}

Evaluation of Bone Marrow Iron Stores

In bone marrow aspirates, hemosiderin appears as goldenyellow refractile granules. More often, the specimen is stained by the Prussian blue method, which renders hemosiderin blue.¹⁰³ Experienced observers can grade the marrow hemosiderin stores from 0 to 6+ (Table 22.8).¹⁰⁴ Normal marrow is graded 1+ to 3+. In iron deficiency, marrow hemosiderin is absent; in the anemia of chronic disorders, iron is always present, most often of grade 2 or 3+, but sometimes 4 or 5+. Iron stores are greatly increased (5 to 6+) in thalassemia major and in sideroblastic anemias. Nowadays the marrow assessment of iron is used much less, because serum ferritin provides a simple measurement that correlates with clinical iron states in the anemia of chronic disease and in iron deficiency states.

FIGURE 22.12. Measurements of serum ferritin in uncomplicated iron deficiency, inflammation, liver disease, and iron overload. Geometric mean values for each group (horizontal line). Patients with iron deficiency (total iron-binding capacity >400 $\mu\text{g}/100\text{ ml}$ and transferrin saturation below 16% or absent marrow iron or both) (open circles). Normal range (shaded area). From Lipshitz D, Cook JD, Finch CA. A clinical evaluation of serum ferritin as an index of iron stores. *N Engl J Med* 1974;290:1213-1216, with permission.

Transferrin Receptors

Transferrin receptors (TfRs) are disulfide-linked transmembrane proteins that facilitate the entry of transferrin-bound iron into

P.602

cells (Chapter 23). A soluble, truncated form of the protein can be detected in plasma, and its immunologic quantification can be useful in detecting iron deficiency and distinguishing it from the anemia of chronic disease. Values in iron deficient subjects are clearly increased, and are typically not increased in uncomplicated anemia of chronic disease.^{105,106,107} Therefore, TfR determination may be useful in distinguishing iron deficiency from the anemia of chronic disease, but must be interpreted in association with the ferritin concentration.⁹⁶ It has been proposed that the ratio of serum TfR concentration to the logarithm of the serum ferritin concentration has a better capacity to distinguish iron deficiency from the anemia of chronic disease than does the unadjusted serum TfR concentration¹⁰⁸ (Fig. 22.13). Serum TfR levels also vary with the total mass of red cell precursors. Therefore, the value increases in hemolytic anemia, thalassemia, and polycythemia, and decreases in hypoplastic anemia and renal failure.⁷⁶

TABLE 22.8 CRITERIA FOR GRADING IRON STAINS IN BONE MARROW ASPIRATES

Grade	Criteria	Iron Content (µg/g)
0	No iron granules observed	42 ± 23
1+	Small granules in reticulum cells, seen only with oil-immersion lens	130 ± 50
2+	Few small granules visible with low-power lens	223 ± 75
3+	Numerous small granules in all narrow particles	406 ± 131
4+	Large granules in small clumps	762 ± 247
5+	Dense, large clumps of granules	1,618 ± 464
6+	Very large deposits, obscuring marrow detail	3,681 ± 1,400

Other Tests to Assess Iron Metabolism

Erythrocyte Zinc Protoporphyrin

Red cell precursors normally synthesize slightly more protoporphyrin than is needed for heme synthesis. The excess remains with the cell throughout its lifespan and has been called free erythrocyte protoporphyrin (FEP). When iron is not available for heme synthesis, protoporphyrin accumulates in excess as zinc protoporphyrin. Measurement of FEP is available as a screening test for iron deficiency, and the test requires only a drop of blood and 1 minute of processing.^{51,109} The level of FEP increases dramatically in iron deficiency and is a sensitive laboratory abnormality in this condition.^{51,109,110,111,112} The erythrocyte zinc protoporphyrin content also is greatly increased in lead poisoning but is normal in thalassemia.^{109,110}

Liver Iron Stores

Iron stores can also be estimated by liver biopsy using both histochemical and chemical methods of analysis.^{113,114} Even gross inspection of a Prussian blue-stained biopsy specimen can provide a reasonably reliable estimate of iron stores.¹¹⁵ Criteria for grading the preparations from 1 to 4+ have been established,^{113,114,116} and these correlate well with chemical analysis. Chemical analysis has been important in evaluating hemochromatosis and transfusion iron overload, because a disproportionate amount of iron is in parenchymal cells in the form of ferritin, which does not stain with Prussian blue.¹¹⁷ Measurement of hepatic iron stores has been used mainly to assess iron overload states, because the correlation between serum ferritin and true tissue iron content is not as good when there is elevated tissue iron content. Currently, however, magnetic resonance imaging using T2* technology is replacing liver biopsy as a noninvasive way to measure liver iron content.^{118,119}

FIGURE 22.13. Ratio of serum transferrin receptor concentration [TfR] to \log_{10} serum ferritin concentration [Ferr] in anemic patients with iron deficiency (IDA; $n = 19$), anemia of chronic disease (ACD; $n = 65$), and features of both syndromes (IDA/ACD; $n = 7$). Bars indicate the mean (dot) and 95% confidence intervals of values in the three groups.

Urinary Iron Excretion

Storage iron has been evaluated by urinary excretion of iron after the administration of a chelating agent.^{120,121,122,123} The chelator most commonly used for this purpose is deferoxamine. A rough correlation exists between iron stores and urinary iron excretion after deferoxamine administration.

Disorders of Hemoglobin Synthesis

The Hb disorders associated with microcytosis include the thalassemias and certain structural Hb variants.

The thalassemias are a group of inherited disorders in which synthesis of one of the normal polypeptide chains of globin is severely deficient (Chapter 34). In mild forms of the disease (thalassemia minor), hypochromia and microcytosis are prominent, whereas anemia is absent or mild. In other thalassemic disorders, including homozygous β -thalassemia (β -thalassemia major) and Hb E β -thalassemia, hypochromic, microcytic anemia is usually quite severe.

Some structurally abnormal Hb also may be associated with moderate microcytosis. This is particularly characteristic of patients carrying an Hb E gene. Heterozygotes for this hemoglobinopathy typically have microcytosis without anemia.^{124,125,126} Homozygotes have a greater degree of microcytosis and either mild or no anemia.^{53,124,125} Like thalassemia, Hb E diseases are characterized by reduced β -chain synthesis.¹²⁷ Microcytosis also occurs in homozygous Hb C disease.^{128,129}

The possibility of thalassemia minor is often raised by finding that the microcytosis is more severe than might be expected for the mild degree of anemia. In addition, basophilic stippling and target cells tend to be more prominent in thalassemia than in iron deficiency. An important feature of thalassemia trait-like conditions (which include the Hb E syndromes) is that the RBC count often is very high normal to elevated despite having anemia and small RBC. This characteristic has allowed several different measures for differentiating iron deficiency from thalassemia trait and Hb E disorders. One of the most useful is a modification of the Mentzer index,¹³⁰ which is based on the MCV and RBC count:

MCV/RBC (10^6) > 14 (suggestive of iron deficiency)

MCV/RBC (10^6) 12 to 14 (indeterminate)

MCV/RBC (10^6) < 12 (suggestive of thalassemia trait disorders)

RDW, a measure of anisocytosis derived from erythrocyte volume distribution, has been advocated for distinguishing iron deficiency from thalassemia minor in patients with microcytosis.^{49,58,61,131} Anisocytosis is an early and prominent finding in iron deficiency, often detectable before significant microcytosis, hypochromia, or even anemia is apparent. In contrast, anisocytosis tends to be absent or mild in thalassemia minor. The normal value for RDW is $13.4 \pm 1.2\%$ (mean, 2 SD), and the upper limit of normal is 14.6% (40). In iron deficiency, the value is $16.3 \pm 1.8\%$, whereas in β - or α -thalassemia minor, the value is normal ($13.6 \pm 1.6\%$). An increased RDW appears to be 90% to 100% sensitive for iron deficiency but only 50% to 70% specific.¹³² An increased value for RDW in an otherwise normal complete blood count most often represents early iron deficiency, but other nutritional deficiencies are also possible causes.

P.603

Homozygous hemoglobinopathies, especially Hb C¹²⁵ and Hb E,^{53,126} tend to be microcytic and normochromic, and many target cells are apparent in the blood smear (Chapter 34).

Distinguishing homozygous β -thalassemia (β -thalassemia major) from β -thalassemia minor is rarely a problem, because the former is accompanied by signs of hemolysis and ineffective erythropoiesis; there also are characteristic findings on the blood smear, including nucleated red cells, extreme anisocytosis and poikilocytosis, and target cells (Chapter 34). However, it is a common diagnostic problem to distinguish patients with β -thalassemia trait from those with iron deficiency. In almost all cases of β -thalassemia trait, the fraction of Hb A₂ is increased, whereas the value for Hb A₂ is normal or decreased in iron deficiency.¹³³ An exception is that if a patient with β -thalassemia trait happens to be iron deficient at the time of evaluation, the Hb A₂ be normal. When iron replete, the same patient's Hb A₂ will be elevated as expected.

α -Thalassemia syndromes result from decreased α -globin chain synthesis that is directed by four structural genes. Four different α -thalassemia syndromes have been recognized on chromosome 16. Silent carrier state (α -thalassemia II) individuals lack one α globin gene; the α , β -globin chain synthetic ratio is decreased from unity, but these individuals are hematologically normal and have no clinical problems. α -Thalassemia trait (α -thalassemia I) individuals lack two α -globin genes, α -globin synthesis is impaired, and there is a mild hypochromic microcytic anemia. Hb H disease is caused by the deletion of three α -globin genes, and the consequence of this is a mild to moderate hemolytic anemia. Beyond the neonatal period, the unbalanced chain synthesis leads to an excess in β -globin chains which form Hb H (β_4 tetramers). Hb H is mildly unstable, particularly in the presence of oxidant stress, thereby causing intermittent hemolysis. Homozygous α -thalassemia (hydrops) is due to a deletion of all four α -globin genes, resulting in severe anemia because of the complete absence of α -globin chains. This disorder is incompatible with life, and fetuses are aborted early, are stillborn, or die within the first few hours of life.

A common clinical problem is to identify α -thalassemia trait, which has a similar presentation to β -thalassemia trait and to iron deficiency. The diagnosis often is a presumptive one, made after excluding iron deficiency, β -thalassemia trait, and any other abnormal Hb. The α -thalassemia syndromes occur primarily in those of Asian and African descent, and it is of interest that in Africans with α -thalassemia trait, the globin gene deletions occur on different chromosomes (i.e., trans deletions), whereas in Asians with α -thalassemia trait, the gene deletions occur on the same chromosome (i.e., cis

deletion). As a consequence of these racial differences, Hb H disease and homozygous α -thalassemia occur only in Asians. Moreover, virtually all Africans with α -thalassemia have α -thalassemia trait (Chapter 34).

GENERAL DIAGNOSTIC APPROACH TO HEMOGLOBINOPATHIES AND THALASSEMIAS

The clinical and laboratory features of specific thalassemia and hemoglobinopathy syndromes are discussed in the chapters addressing those syndromes. Thalassemia and hemoglobinopathy syndromes are suspected in patients with microcytosis, in patients with unexplained hemolytic anemia, and in patients with the red cell abnormalities suggestive of hemoglobinopathies, such as sickle cells or the characteristic inclusions of Hb C disease. The principal tool in the identification of hemoglobinopathies and thalassemia is the hemoglobin electrophoresis. Hb C, Hb E, Hb S, and Hb H can be detected by electrophoresis. The presence of increased amounts of Hb A₂ and/or Hb F indicates β -thalassemia variants. The most common approach to Hb electrophoresis uses cellulose acetate at alkaline pH (usually 8.2-8.6); however, Hb A₂ and Hb C migrate to the same position, and must be distinguished by electrophoresis at an acidic pH on citrate agar. Specific quantitative tests using alkali denaturation for Hb F or ion-exchange microcolumns for Hb A₂ are widely available. Isoelectric focusing can separate a number of Hb types not clearly distinguished in cellulose acetate or citrate agar, and high pressure liquid chromatography (HPLC) techniques have replaced electrophoretic methods in many reference laboratories. DNA sequencing is often employed in the analysis of rare or novel Hb variants.

α -Thalassemia syndromes are not associated with increases in Hb A₂ and Hb F, and thus are not detectable on electrophoresis unless three α genes are deleted, resulting in Hb H disease. For this reason, the diagnosis of α -thalassemia trait is usually made presumptively, having excluded iron deficiency and β -thalassemia. Specific DNA-based testing is available, but it is seldom used for routine diagnostic purposes. Its major value is in prenatal diagnosis, and the counseling of potential parents at risk for having children with homozygous α -thalassemia. Unstable Hbs are detected by the heat denaturation test.

Sideroblastic Anemias

The sideroblastic anemias are due to acquired and hereditary disorders of heme synthesis (Chapter 24). A classic morphologic feature of this type of anemia, as seen in the peripheral blood smear, is the presence of erythrocyte dimorphism (Fig. 22.4E), with a microcytic population of cells mixed with a normal red cell population and the presence of occasional, heavily stippled, hypochromic cells. In hereditary (X-linked) sideroblastic anemia, the anemia and microcytosis are pronounced (Table 22.7), and these changes are accompanied by considerable anisocytosis and poikilocytosis. The serum iron concentration usually is elevated, and the TIBC is increased. In all cases of sideroblastic anemia, regardless of the specific etiology, impaired heme synthesis leads to retention of iron within the mitochondria. Morphologically, this is seen in marrow aspirates which reveal many nucleated red cells with iron granules (i.e., aggregates of iron in mitochondria) that have a perinuclear distribution.^{134,135} These unusual cells, known as ringed sideroblasts, are found only in pathologic states and are distinct from the sideroblasts (erythroblasts with diffuse cytoplasmic ferritin granules) seen in 30% to 50% of normal RBC precursors in marrow. Most common sideroblastic anemias occur in middle age and later life, and these acquired disorders can be idiopathic, secondary to drugs, alcohol, or myeloproliferative disorders (Table 22.6). In addition, there are rare congenital sideroblastic anemias that conform to an X-linked pattern of inheritance, usually occurring in males, although skewed lyonization has resulted in affected females. Autosomal-dominant and sporadic cases also occur. Several different genetic mutations have been identified in these congenital sideroblastic anemias.¹³⁶ Severe anemias are recognized in infancy or early childhood, whereas milder cases may not become apparent until early adulthood or later. Patients may present with pallor, icterus, moderate splenomegaly, or hepatomegaly. Iron overload is a major complication of this disorder. In some cases in which there is little or no anemia, there still may be clinical evidence of iron overload (i.e., diabetes mellitus and liver dysfunction).

APPROACH TO NORMOCYTIC ANEMIA

Normocytic anemias are those in which the values for MCV are within normal limits, between 80 and 100 fl in adults. At times, however, the anemias that fall into this category also may be macrocytic or microcytic. For example, the anemia associated with hypothyroidism and liver disease may be either normocytic or slightly macrocytic. Also, because of reticulocytosis, the anemia

P.604

associated with acute hemorrhage or chronic hemolysis may be normocytic or slightly macrocytic. The anemia of chronic disorders, although most often normocytic, is sometimes microcytic, and its pathogenesis is best understood in the context of microcytic anemias, as described above. Lastly, iron deficiency early in the course of anemia may be normocytic before becoming microcytic.

The normocytic anemias are not related to one another by common pathogenetic mechanisms. In many instances, anemia is only of incidental importance, a minor manifestation of a systemic disease with other, more serious consequences. Importantly, however, sometimes anemia is the first evidence of disease and the sign leading to discovery of the underlying disorder.

Despite the varied etiologic background and the often incidental nature of the normocytic anemias, they can be classified in a way that forms a basis for diagnostic investigation (Fig. 22.14). As a first step, it should be determined whether the erythropoietic response is appropriate to the degree of anemia. When bone marrow function is unimpaired and the iron supply is ample, erythropoiesis can increase manyfold. In most cases, marrow examination is not necessary to determine that the erythropoietic response is adequate, because reticulocytosis may be prominent, and polychromatophilic macrocytes may be detected on routinely stained smears. These manifestations of appropriate marrow response are typical of hemolytic anemia and posthemorrhagic anemia. The history, physical examination, and signs of excessive erythrocyte destruction (e.g., hyperbilirubinemia) provide the information necessary to differentiate these two conditions. The diagnostic approach to anemias due to hemolysis and after acute hemorrhage are discussed separately below.

When anemia is apparent but the erythropoietic response is less than appropriate, most likely the underlying disorder directly or indirectly affects the bone marrow. Indirect effects should be investigated first, because often a diagnosis can be made without resorting to marrow aspiration and biopsy. For example, several disorders are associated with reduced secretion of erythropoietin (Table 22.9). In these conditions, screening tests usually uncover an underlying systemic disease, and for this purpose, renal function, liver function, and thyroid status should be assessed by use of appropriate biochemical tests. Although severe protein-calorie malnutrition is accompanied by reduced erythropoietin secretion and a mild normocytic anemia, such undernutrition is rare in developed countries and thus is not likely to be confused with other systemic disorders. The anemia of chronic disease typically presents as a normocytic anemia with low reticulocytes. This can be recognized by the underlying inflammatory state and the previously described iron studies. One of the causes of this is thought to be a blunted erythropoietic response due to the presence of inflammatory cytokines (Chapter 41).

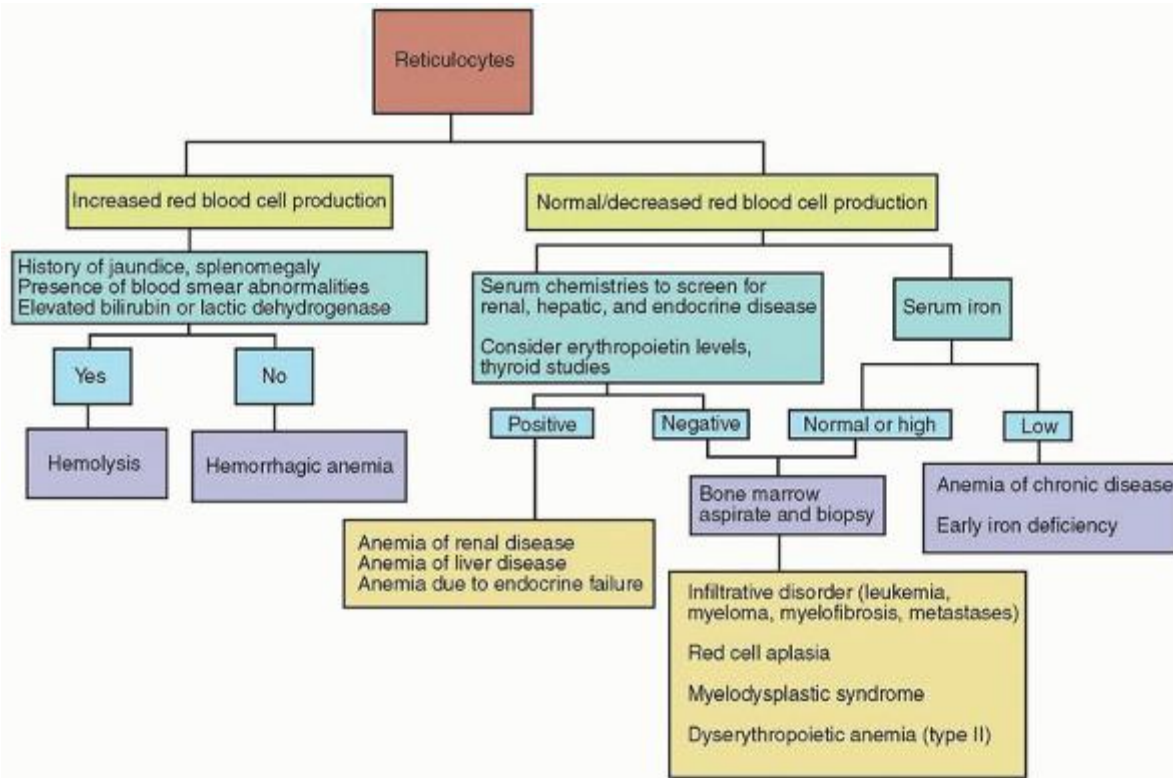

FIGURE 22.14. Diagnostic approach to a patient with normocytic anemia.

Normocytic anemia with marked reticulocytopenia also is a characteristic of pure red cell aplasia (PRCA). Acquired PRCA in adults represents a relatively rare group of disorders usually occurring in the fifth to seventh decades of life (Chapter 39). The anemia can occur as a primary disorder or secondary to some other disease. Early studies suggested an association with thymoma, but more recent data indicate this is much less common. Most cases of PRCA are seen with a variety of hematologic malignancies (in particular chronic lymphocytic leukemia) and also with nonhematologic malignancies,

rheumatoid arthritis, systemic lupus erythematosus, and in association with a variety of drugs and chemicals. Laboratory data reveals isolated anemia, reticulocytopenia, and a bone marrow almost completely void of erythroblasts. The remainder of the CBC is normal.

Transient erythroblastopenia of childhood (TEC) is a form of RBC aplasia occurring in young children, caused by transient antibody-mediated suppression of normal erythropoiesis that frequently follows a viral infection (Chapter 39). In contrast to Diamond-Blackfan syndrome, there are no congenital abnormalities and no abnormal RBC features. The natural history of transient erythroblastopenia of childhood is one of spontaneous recovery over a few weeks.

P.605

TABLE 22.9 CLASSIFICATION OF THE NORMOCYTIC ANEMIAS

Anemia associated with appropriately increased erythrocyte production

Posthemorrhagic anemia

Hemolytic anemia

Decreased erythropoietin secretion

Impaired source:

Renal: anemia of renal insufficiency

Hepatic: anemia of liver disease

Reduced stimulus (decreased tissue oxygen needs)

Anemia of endocrine deficiency

Protein-calorie malnutrition

Anemia of chronic disorders

Anemia with impaired marrow response

Red blood cell aplasia

Acquired pure red cell aplasia in adults

Transient erythroblastopenia of childhood

Transient aplastic crises associated with hemolysis

Aplastic anemia (pancytopenia)

Bone marrow infiltrative disorders

Leukemia

Myeloma

Other myelophthisic anemias

Myelodysplastic anemias

Congenital dyserythropoietic anemia ([CDA] type II)

Aplastic crises with hemolytic anemia is a self-limiting form of red cell aplasia seen in patients with chronic hemolytic anemia. It is characterized by a rapid decrease in the steady-state Hb concentration and a very low reticulocyte count (see Approach to Hemolysis).

When the normocytic anemia with reticulocytopenia is associated with leukopenia and thrombocytopenia, there should be suspicion for intrinsic marrow disease due to aplastic anemia, leukemia, myelofibrosis, or myelophthisis. Morphologic abnormalities suggestive of marrow infiltration found on the blood smear include nucleated red cells, teardrop poikilocytes, immature leukocytes, and large, bizarre platelets or megakaryocyte fragments (Fig. 22.6). When such

changes are detected, as well as in any patient with anemia along with other cytopenias, marrow aspiration and biopsy should be performed.

Of the different congenital dyserythropoietic anemias, type II CDA is the most common, and it is the one that almost always presents as a normocytic anemia. This disorder is recognized by distinct multinuclearity of the marrow normoblasts (Chapter 40).

APPROACH TO HEMOLYSIS

Hemolytic disorders are characterized by signs of accelerated erythrocyte destruction together with those of vigorous blood regeneration. Under maximal stimulation, the normal marrow is capable of undergoing hyperplasia until its production rate increases approximately six to eight times.¹³⁷ With optimal marrow compensation, the survival of red cells in the circulation can decrease from the normal 120 days to as few as 15 to 20 days without anemia developing. Such an increase in destruction and production of erythrocytes can result in a compensated hemolytic state without anemia being present. In this regard, it is of interest that a significant fraction of patients with hereditary spherocytosis patients are not anemic. However, when red cell survival is so short that anemia develops despite a vigorous erythropoietic response, the term hemolytic anemia is appropriate.

Pathogenesis and Classification

Disorders associated with hemolytic anemia have been classified in various ways, none of which is entirely satisfactory. On clinical grounds, hemolytic anemias have been divided into acute and chronic forms, but such a division is of limited usefulness because acute episodes may develop during the course of chronic hemolytic disorders. Of somewhat greater use is a classification based on the site of hemolysis: whether it is predominantly within the circulation (intravascular) or within tissue macrophages (extravascular). Most hemolytic diseases are characterized by extravascular red cell destruction. The intravascular hemolytic disorders are accompanied by unique manifestations, such as hemoglobinemia, hemoglobinuria, and hemosiderinuria, and this type of hemolysis is easily recognized (Table 22.10).¹³⁸

Hemolytic disorders also may be considered to be caused by an intrinsic defect in the cell itself or by extrinsic agents acting on otherwise normal red cells. It is this classification which generally is most useful to the clinician (Table 22.11). Most intrinsic defects are inherited, whereas the extrinsic ones are acquired. Exceptions to this generalization are few; these include paroxysmal nocturnal hemoglobinuria (Chapter 31), an acquired disorder characterized by an intrinsic red cell defect. Also, certain inherited intrinsic defects (e.g., the most common form of glucose-6-phosphate dehydrogenase [G6PD] deficiency) are associated with no ill effects in the absence of an extrinsic agent, usually an infection or exposure to a drug (see Chapter 28).

Intrinsic and extrinsic abnormalities originally were defined by performing cross-transfusion erythrocyte survival studies. When normal erythrocytes are transfused to patients with an extrinsic cause for hemolysis, the donated cells are destroyed as rapidly as the patient's own cells. On the other hand, when the patient's RBCs are removed from their unfavorable environment and transfused to a normal recipient, their survival time is normal. In contrast, when the disorder is due to an intrinsic red cell defect, the RBCs of the patient, when given to a normal recipient, are removed from the circulation more rapidly than those of the recipient; the normal erythrocytes, if transfused into the patient, maintain a normal lifespan. While such cross-transfusion experiments played an important role in clarifying the pathogenesis of various hemolytic disorders, obviously they cannot be used in the evaluation of patients.

The intrinsic disorders of the erythrocyte are due to defects affecting the red cell membrane (Chapter 27), disorders of cell metabolism (Chapter 28), or various Hb abnormalities (Chapters 33, 34 and 35) (Table 22.11).

The acquired hemolytic anemias are further subclassified on the basis of the extrinsic factors causing hemolysis. These include antibodies (Chapters 29 and 30) and other nonimmune causes

P.606

(Chapter 32), including physical trauma, infectious agents, physical agents, chemical agents, hypophosphatemia, and liver disease (spur cell anemia). A separate category is needed for paroxysmal nocturnal hemoglobinuria, which is unique among the acquired hemolytic anemias in that it is related to an intrinsic abnormality of the red cell (Chapter 31).

TABLE 22.10 HEMOLYTIC ANEMIAS CHARACTERIZED BY SIGNIFICANT INTRAVASCULAR RED CELL DESTRUCTION

Paroxysmal nocturnal hemoglobinuria

Erythrocyte fragmentation disorders

Transfusion reactions resulting from ABO isoantibodies
Paroxysmal cold hemoglobinuria
Acquired autoimmune hemolytic anemia (occasionally)
Associated with certain infections
Blackwater fever in falciparum malaria
Clostridial sepsis
Caused by certain chemical agents
Arsine poisoning
Snake and spider venoms
Drug reactions with glucose-6-phosphate dehydrogenase (G6PD) deficiency
Intravenous administration of distilled water
Thermal injury

TABLE 22.11 CLASSIFICATION OF MOST COMMON CAUSES OF HEMOLYSIS

Acquired Hemolytic Disorders

Immunochemolytic anemias

Autoimmune hemolytic anemia
Hemolytic disease of the newborn
Transfusion of incompatible blood

Traumatic and traumatic hemolytic anemia

Prosthetic valves and other cardiac abnormalities
Hemolytic uremic syndrome (HUS)
Thrombotic thrombocytopenic purpura (TTP)
March hemoglobinuria
Disseminated intravascular coagulation (DIC)

Infection

Protozoa (Malaria, Toxoplasmosis, Leishmaniasis, Babesiosis)
Bacteria (Clostridial infection, cholera, bartonellosis, typhoid, etc.)

Other causes

Paroxysmal nocturnal hemoglobinuria (PNH)
Spur cell anemia in liver disease
Associated with hemodialysis and uremia
Thermal red blood cell (RBC) injury
Hypophosphatemia
Snake venoms

Inherited Hemolytic Disorders

RBC Membrane abnormalities

Hereditary spherocytosis

Hereditary elliptocytosis syndromes

Hereditary stomatocytosis

Hereditary xerocytosis

RBC Enzyme disorders

Glucose-6-phosphate dehydrogenase (G6PD) deficiency

Pyruvate kinase (PK) deficiency

Glucose-phosphate isomerase (GPI) deficiency

Pyrimidine 5' nucleotidase deficiency

RBC Hemoglobin disorders

Sickle cell anemia syndromes

Thalassemia syndromes

Unstable hemoglobin disorders

Each of these different hemolytic anemias is discussed in detail elsewhere in this book. The remainder of this section focuses on the general clinical and laboratory features that are common to most congenital and acquired hemolytic anemias.

Clinical Features of Congenital Hemolytic Anemia

Degree of Anemia

The severity of anemia varies greatly, even among patients with the same congenital disorder. Most commonly, the anemia with congenital hemolytic disorders is mild to moderate because the shortened erythrocyte survival is partially offset by increased activity of the bone marrow. Often, patients accommodate remarkably well to the anemia and may exhibit few signs or symptoms. Consequently, detection can be delayed until later in childhood and discovered incidentally. Moreover, some patients have no anemia at all. The disease may then remain unsuspected until late in adult life unless jaundice, a crisis, or complications of gallbladder disease draw attention to the condition. Sometimes, such cases are discovered only in the course of a family study.

In some congenital hemolytic disorders, such as homozygous β -thalassemia, the rate of red cell destruction far exceeds the erythropoietic capacity of the marrow, and these individuals usually have a very severe anemia requiring life-long red cell transfusions.

Jaundice

Jaundice often is first noted in the neonatal period,¹³⁹ and phototherapy frequently is used to reduce the hyperbilirubinemia and, sometimes, exchange transfusions are required. In some older children and adults with congenital hemolytic anemia, icterus is absent or mild enough to pass unnoticed. Careful inquiry often elicits a history of episodes of jaundice or the passing of dark urine associated with trivial infections. In other cases, jaundice is persistent but never becomes intense. Often, slight scleral icterus is the only sign of hemolytic disease. As noted earlier, the jaundice of hemolytic disease is acholuric; the bilirubin, being unconjugated, is not excreted in the urine. Furthermore, pruritus is absent. These features help to distinguish the icterus of hemolytic disease from that found with disorders of the hepatobiliary system.

Aplastic Crises

Aplastic crises result from transient failure of red cell production (Fig. 22.15) caused by infection with the type B19 human parvovirus.^{140,141,142} and¹⁴³ The same virus also causes erythema infectiosum (fifth disease, a common childhood exanthem)^{144,145} and may cause an acute polyarthropathy syndrome in adults as well as aseptic meningitis¹⁴⁶ and fetal death with hydrops fetalis.^{147,148} Parvovirus infection may occur sporadically but most often is an epidemic disease that can affect several family members simultaneously or multiple people in a large geographic area. Schoolage children (age 5 to 10 years) are most at risk for parvovirus infection,¹⁴³ but cases have been reported of parvovirus infection in young adults.^{143,149} Any patient with moderately severe chronic hemolytic disease who becomes infected with parvovirus is at

risk for an aplastic crisis. Blood Hb concentrations fall several grams, sometimes to life-threatening levels,¹⁴⁹ and the reticulocyte count falls abruptly, usually to less than 1%. The magnitude of the crisis depends on the severity of the underlying hemolytic process. In most cases, leukocyte and platelet counts are unaffected, but neutropenia and thrombocytopenia can occur and, rarely, may be severe.¹⁴² The bone marrow is cellular, but erythroid hypoplasia is the characteristic finding; in particular, the more mature erythrocyte precursors tend to disappear. Giant pronormoblasts may be observed. Recovery is heralded by reticulocytosis. The entire episode, from onset of symptoms to reappearance of reticulocytes, lasts approximately 10 to 12 days

P.607

in subjects with normal immunologic responses, but may persist much longer in patients with defective or suppressed immune systems.¹⁵⁰ Parvovirus infection also produces erythroid aplasia in normal subjects, but the decrease in Hb concentration is minimal when erythrocyte survival is normal,¹⁵¹ and such small changes go undetected. During the acute phase of aplastic crisis, parvovirus DNA often can be detected in the serum by polymerase chain reaction assays.¹⁴⁴ The appearance of a specific immunoglobulin (Ig) M (IgM) antibody in serum is a marker of recent infection.¹⁴² It is replaced by an IgG antibody that persists for years and is found in 60% of normal subjects. A single infection apparently confers life-long immunity. However, parvovirus antibody titers are only helpful in the immunocompetent.

FIGURE 22.15. Severe aplastic crisis in a patient with hereditary spherocytosis who previously had well-compensated hemolysis. Note the profound reticulocytopenia during the early phases of the reaction, followed by reticulocytosis. Hb, hemoglobin. (Data plotted from Owren P. Congenital hemolytic jaundice. The pathogenesis of the “hemolytic crisis.” *Blood* 1948;3:231-248.)

Splenomegaly

The spleen typically is enlarged in patients with congenital hemolytic anemias, except for individuals with sickle cell anemia older than 5 years of age. Most often, the degree of enlargement is mild to moderate. At times, splenomegaly leads to discovery of the disease because the spleen is detected on a routine physical examination. It is not uncommon for children with hereditary spherocytosis to first be recognized by the finding of splenomegaly during a routine physical examination in an otherwise healthy child.

Cholelithiasis

Gallstones and their complications play a significant role in the clinical manifestations of congenital hemolytic anemias. Symptoms of gallbladder disease rarely may be the initial manifestations of a hemolytic process and the ones that bring the illness to the attention of a physician. Gallstones typical of hemolytic anemia are so-called black pigment stones.^{152,153} They differ from brown pigment stones and cholesterol stones, neither of which is associated with hemolysis. The hepatic

bile of patients with hemolytic anemia contains greatly increased amounts and concentrations of unconjugated bilirubin, decreased concentrations of bile acids,^{153,154} and increased concentrations of ionized calcium.¹⁵⁵

The prevalence of cholelithiasis in patients with hemolytic anemia increases with age and with the intensity of the hemolytic process. In a large study series involving Jamaican patients with sickle cell anemia, the prevalence ranged from 8% among patients 16 to 25 years old to 55% in patients older than age 35 years with reticulocyte counts greater than 15%.¹⁵⁶

Leg Ulcers

Chronic ulcerations of the legs are peculiar and uncommon complications of chronic hemolytic disease. They are particularly characteristic of sickle cell anemia (Chapter 33),¹⁵⁷ but also occur in association with other hemolytic disorders,^{158,159,160} and ¹⁶¹ such as hereditary spherocytosis¹⁶² (Chapter 31). The ulcers often are bilateral and tend to involve the areas overlying or proximal to the medial or lateral malleoli. They tend to be chronic or recurrent and, upon healing, leave the skin indurated and pigmented.

Skeletal Abnormalities

When hemolytic anemia is severe during active phases of growth and development, the pronounced expansion of erythroid bone marrow may lead to a tower-shaped skull, thickening and striation of frontal and parietal bones ("frontal bossing"), maxillary and dental abnormalities, and other distortions of bony structures. Such abnormalities are particularly characteristic of severe thalassemia major, the so-called thalassemic facies (Chapter 34). Nowadays it is much less common to see these skeletal malformations, because patients with homozygous β -thalassemia are transfused aggressively with red cells to maintain a higher Hb level, and this suppresses expansion of the erythroid marrow and its subsequent effects on bone structure. However, in patients with thalassemia intermedia, a slightly milder clinical variant not necessitating RBC transfusions, the characteristic bone changes may occur because of the expanded size of the erythroid marrow. The skeletal changes also may occur in patients with sickle cell anemia and in exceptional patients with other forms of congenital hemolytic anemia.¹⁶⁰

Clinical Features of Acquired Hemolytic Anemia

Hemolytic anemia sometimes develops acutely, such as after the transfusion of incompatible blood or the ingestion of an oxidant drug by patients with G6PD deficiency or in association with an acute febrile illness. Some instances of autoimmune hemolytic anemia, thrombotic thrombocytopenic purpura, and other hemolytic disorders may also begin abruptly.¹⁶² Aching pains in the back, abdomen, or limbs are common, as are headaches, malaise, vomiting, shaking chills, and fever.¹⁶² Abdominal pain may be severe, and the accompanying muscular spasm and rigidity may simulate the signs of an acute abdominal condition requiring surgical treatment. Pallor, jaundice, tachycardia, and other symptoms of severe anemia may be prominent.

Acquired hemolytic anemia also can begin insidiously, developing gradually over a period of weeks or months. Cardiovascular adjustments to the anemia may be adequate, and patients may have few symptoms. Pallor, scleral icterus, or a jaundiced complexion may be the first evidence of illness, and often, these signs are noticed by friends or associates before they are appreciated by the patient or the family. As in congenital hemolytic anemia, the course may be interrupted by aplastic crises.¹⁴¹

In other instances, the clinical setting may be dominated by the manifestations of an underlying disease of which the hemolytic anemia is one manifestation. For example, signs and symptoms of lymphoma, lupus erythematosus, or mycoplasma pneumonia may overshadow those of the associated hemolytic process.

Laboratory Features of Hemolysis

The laboratory studies used to identify a hemolytic process include those related to the increase in erythrocyte destruction and those related to the compensatory increase in the rate of erythropoiesis.

Signs of Increased Red Blood Cell Destruction

Serum Bilirubin

The amount of bilirubin in the circulation depends in part on the rate at which the bilirubin is formed and in part on the efficiency with which it is excreted by the liver. Hyperbilirubinemia is a hallmark of hemolytic anemia (Fig. 22.16), although occasionally the serum bilirubin is within the normal range despite brisk hemolytic disease.¹⁶³ The increased serum bilirubin level in hemolysis almost always consists of the unconjugated (indirectreacting) pigment. The conjugated fraction remains within normal limits, and no bilirubin is evident in the urine. Except for during the neonatal period, values greater than 5 mg/dl are unusual in patients with hemolytic anemia and suggest coexisting hepatic dysfunction.

Serum Lactic Dehydrogenase

Serum lactic dehydrogenase (LDH) often is increased in patients with hemolytic anemia, although not to as great an extent as in megaloblastic anemia. The increase in LDH probably results from liberation of the erythrocyte enzyme into the plasma during

P.608

hemolysis.¹⁶³ Increased serum LDH is a nonspecific finding, because it also is elevated in other medical conditions associated with tissue injury.

FIGURE 22.16. Total serum bilirubin values in 48 normal subjects and 72 patients with hereditary spherocytosis. (Data from Mackinney A, Norton NE, Kosower NS. Ascertaining genetic carriers of hereditary spherocytosis by statistical analysis of multiple laboratory tests. *J Clin Invest* 1962;41:554-567, with permission.)

Serum Haptoglobin

When Hb enters the plasma, it binds to haptoglobin, and the complex is removed by hepatocytes. As a result, serum haptoglobin decreases in individuals with hemolytic disease. Moreover, despite the intravascular site of haptoglobin function, this protein becomes depleted in association with both intravascular and extravascular hemolysis, such as sickle cell anemia,¹⁶⁴ hereditary spherocytosis,^{164,165} hereditary elliptocytosis,¹⁶⁶ and pyruvate kinase deficiency.¹⁶⁰ Haptoglobin also disappears in megaloblastic anemia and other conditions with intramedullary hemolysis (ineffective erythropoiesis) (Fig. 22.17).¹⁶⁷ In microangiopathic hemolytic anemias with intravascular hemolysis, low haptoglobin levels are the most sensitive marker of red cell destruction, and may be seen in the absence of anemia or hemoglobinemia).

The interpretation of haptoglobin levels sometimes is complicated by the fact that haptoglobin is an acute phase reactant, the synthesis of which increases in response to inflammatory, infectious, or malignant disease. Haptoglobin values also may fall in association with liver disease because of impaired synthesis and in hereditary deficiency of the protein.

Erythrocyte Survival

The strictest definition of hemolysis requires demonstration that the red cell lifespan is reduced. From a practical perspective, however, erythrocyte lifespan determinations are rarely necessary, because they provide little additional information beyond what can be assessed by more easily obtained data, such as serial observations of the degree of anemia, reticulocytosis, and jaundice. For these reasons, determination of red cell survival is reserved for use in evaluating patients with especially difficult diagnostic problems.

FIGURE 22.17. Serum haptoglobin in hemolytic and nonhemolytic disease. (From Marchand A, Galen RS, Van Lente F. The predictive value of serum haptoglobin in hemolytic disease. *JAMA* 1980;243:1909, with permission.)

Rate of Carbon Monoxide Production

Determinations of the rate of endogenous carbon monoxide production provide accurate assessments of the rate of heme catabolism. With these methods, values of approximately two to ten times the normal rate have been detected in small

groups of patients with hemolytic disease. At the present stage of development, however, these methods are not available for routine clinical use.^{168,169}

Signs of Intravascular Hemolysis

When erythrocytes are destroyed within the circulation, and also when extravascular destruction is so rapid that it exceeds the capacity of the macrophage system, Hb is released into the plasma. The disposal of Hb and its heme group occurs by several mechanisms (Chapter 6), and characteristic laboratory abnormalities are found (Table 22.12).

Hemoglobinemia

At low concentrations, plasma Hb may be measured by means of the benzidine reaction, which allows detection not only of Hb but also of any other heme pigments that may be present. If special precautions are observed to avoid artifactual hemolysis during collection of blood, normal values of less than 1 mg/dl of plasma are found. Plasma usually appears visibly red when Hb exceeds

P.609

50 mg/dl. At levels greater than 100 mg/dl, Hb can be measured directly by the cyanomethemoglobin method.

TABLE 22.12 LABORATORY SIGNS OF HEMOLYSIS

Accelerated red cell destruction
 Decreased erythrocyte lifespan
 Increased heme catabolism
 Increased serum unconjugated bilirubin level
 Increased carbon monoxide production
 Increased rate of urobilinogen excretion
 Increased serum lactate dehydrogenase
 Decreased serum haptoglobin
 Hemoglobinemia
 Hemoglobinuria
 Hemosiderinuria
 Methemalbuminemia
 Decreased serum hemopexin
 Fall in blood hemoglobin level at a rate >1.0 g/dl/wk
 Accelerated erythropoiesis
 Complete blood count
 Reticulocytosis
 Macrocytosis
 Blood smear findings
 Polychromatophilia
 Basophilic, stippling
 Erythroblastosis
 Abnormal red blood cell forms
 Bone marrow (erythroid hyperplasia)

Ferrokinetic (increased plasma iron turnover)**Biochemical (increased erythrocyte creatine)**

Plasma Hb levels are normal in most patients with hereditary hemolytic anemias, including hereditary spherocytosis, but can be increased in severe, acquired, immunohemolytic anemia, at times reaching 100 mg/dl.¹⁷⁰ Particularly high values, up to 1,000 mg/dl, are found only in patients with disorders associated with intravascular hemolysis.¹³⁸

Hemoglobinuria

When plasma Hb exceeds the haptoglobin binding capacity, Hb dimers are excreted into the urine, resulting in hemoglobinuria. Urine that contains Hb ranges from faint pink to deeper red, or even to almost black, similar to a cola beverage.

Hemoglobinuria can be distinguished from hematuria (whole RBCs in the urine) by microscopic examination of a freshly voided urine specimen. Urine also may appear red because of ingestion of certain drugs (Pyridium) or food (beets), or because of porphyrinuria (Chapter 26) or myoglobinuria. Of these various red urinary pigments, only Hb and myoglobin produce a positive reaction in the commonly available tests for occult blood, which are based on the benzidine or orthotolidine reactions.¹⁷¹

Hemoglobinuria must be distinguished from myoglobinuria, which occurs as the result of massive muscle injury.^{172,173} and¹⁷⁴ Myoglobin is a heme pigment of low molecular weight (17,000 Da); it is not bound by haptoglobin and therefore does not accumulate to an appreciable extent in plasma. Thus, inspection of the plasma can help to distinguish myoglobinuria from hemoglobinuria, the presence of a red color in the plasma favoring the latter. More precise identification is accomplished by spectroscopic analysis.

Urine Hemosiderin and Urinary Iron Excretion

Hb in the glomerular filtrate is partially reabsorbed by the proximal tubular cells, and the Hb iron is incorporated into ferritin and hemosiderin. Subsequently, the iron-containing tubular cells are sloughed into the urine. Hemosiderinuria, therefore, constitutes reliable evidence that hemoglobinemia has occurred in the recent past.^{138,170} After an acute episode of intravascular hemolysis, however, several days may pass before increased iron excretion can be detected. Moreover, the abnormality may persist for some time after the episode has terminated. In most conditions associated with chronic intravascular hemolysis, such as in some of the fragmentation hemolysis syndromes, increased iron excretion is a constant finding, whereas hemoglobinuria occurs only intermittently. Hemosiderinuria may be detected by means of a qualitative test based on the Prussian blue reaction.¹⁷⁰

Methemalbumin and Hemopexin

Hb in plasma is readily oxidized to methemoglobin, from which the heme group easily detaches. The liberated heme binds to hemopexin and also to albumin, forming methemalbumin. Hemopexin-heme and methemalbumin impart a coffee-brown color to plasma. With either combination, a spectral absorption band is observed at 620 to 630 nm, which, unlike a similar band in methemoglobin, does not disappear if hydrogen peroxide is added. With the addition of ammonium sulfide, the 620- to 630-nm band disappears and a band at 558 nm forms (Schumm test).¹⁷⁵ Low hemopexin values are seen in thalassemia major, sickle cell anemia, and the fragmentation hemolytic anemia that follows cardiac surgical procedures. The measurement of hemopexin is seldom used to assess hemolytic anemia.

Signs of Accelerated Erythropoiesis

Laboratory signs of increased erythropoiesis are almost always present in patients with chronic hemolytic disease. In patients who have had an acute hemolytic episode, signs of increased red cell production appear after 3 to 6 days (Table 22.12). These same signs of increased RBC production also occur after hemorrhage and after specific therapy for anemia caused by iron, folate, or vitamin B₁₂ deficiency.

Reticulocytosis

An increased number of reticulocytes continues to be the most readily available and most often used index of accelerated erythropoiesis. In cases of hemolytic anemia, the erythrocyte production rate and the absolute reticulocyte count is usually greatly increased when hemolysis is severe enough to produce anemia. In most types of hemolytic anemia, the reticulocyte count consistently increases to levels that correlate fairly well with the severity of the process. Exceptions occur during aplastic crises. Also, some patients with acquired immunohemolytic anemia may have normal reticulocyte counts, and in one report, values of less than 2% were found in 26% of 35 such patients.¹⁶² In these cases, it is thought that the autoantibodies are directed against marrow erythroid precursors as well as circulating erythrocytes.

Morphologic Findings in the Blood

When reticulocytes are increased, polychromatophilia and fine basophilic stippling are apparent on routinely stained smears of blood. Macrocytosis is found in association with most hemolytic disorders because of erythropoietin-mediated stimulation of Hb synthesis and because prematurely released (shift) reticulocytes are larger than normal erythrocytes. Exceptions occur in hereditary spherocytosis and sickle cell anemia, diseases in which the intrinsic defect of the cell tends to decrease its size.

When hemolysis is brisk, nucleated erythrocytes may be found in the blood (erythroblastosis), usually in numbers below 1% of all the nucleated cells. In infants, however, erythroblastosis may be more striking, especially in hemolytic disease of the newborn.

P.610

Neutrophilic leukocytosis and thrombocytosis may accompany hemolytic anemia. These findings tend to be most common and most pronounced in patients with acute hemolytic anemias. Platelets are not only numerous but also large. The changes are less pronounced in chronic hemolytic processes.

Bone Marrow

The major alteration in the bone marrow in hemolytic anemia is erythroid hyperplasia, as manifested by a reduction in the myeloid to erythroid ratio.

Laboratory Tests Useful in the Differential Diagnosis of Hemolysis

Specific Morphologic Abnormalities

Detection of certain distortions of red cell shape is of particular diagnostic use because their presence suggests only one or a few entities. Descriptive features of certain such abnormal red cells are presented in Table 22.13 and illustrated in Figures 22.18 and 22.19.

Spherocytes, erythrocytes that lack an area of central pallor (Fig. 22.18B), are the hallmark of hereditary spherocytosis. They are also found in most patients with acquired immunohemolytic anemias (Fig. 22.18C), thermal injury, hypophosphatemia, or certain kinds of chemical poisoning.

Oval cells or elliptocytes (Fig. 22.18D) are the sine qua non of common hereditary elliptocytosis, which usually is a morphologic curiosity, but not associated with significant hemolysis. However, some hereditary elliptocytosis variants are also associated with marked poikilocytosis (Fig. 22.18E and F), and these individuals have significant hemolytic anemia.

Stomatocytes (Fig. 22.18G), which suggest a disturbance in red cell cation content, are found in association with a rare inherited hemolytic disease and also in liver disease.

TABLE 22.13 MORPHOLOGIC ABNORMALITIES IN HEMOLYTIC ANEMIA

Cell	Description	Clinical Disorders
Spherocyte	Spheroid RBC with no central pallor	Hereditary spherocytosis Immunohemolytic anemia Burns
Elliptocytes	Oval RBC	Hereditary elliptocytosis Megaloblastic anemia
Stomatocytes	Uniconcave red cell; slitlike rather than circular area of central pallor	Hereditary stomatocytosis Alcoholism
Acanthocytes	5-10 spicules of various lengths, irregular in spacing and thickness	Spur cell anemia with liver disease Abetalipoproteinemia
Echinocytes	10-30 spicules evenly distributed over cell surface	Uremia
Sickle cells	RBC with sickle shape	Sickle cell anemia

Target cells	Solid area in center of central pallor	Thalassemia Hemoglobin C disorders Liver disease Lecithin-cholesterol acyltransferase deficiency Postsplenectomy
Schistocytes	Triangular, helmet-shaped, fragmented, or greatly distorted cell; small	Microangiopathic anemia Turbulent blood flow Hemolytic uremic syndrome

RBC, red blood cell.

Acanthocytes indicate disturbed erythrocyte lipid composition; they occur in association with abetalipoproteinemia and the spur cell anemia that occasionally accompanies hepatic cirrhosis.

Echinocytes (sea urchin cells) are a nonspecific abnormality and are also found in uremia.

Sickle cell anemia was named after the unmistakable sickle-shaped red cells that characterize that disorder (Figs. 22.19A,B).

Target cells (Fig. 22.19C) are characteristic of thalassemia, Hb E syndromes, and Hb C disorders. Target cells also occur in nonhemolytic states, such as obstructive jaundice and after splenectomy.

Schistocytes, helmet cells, or other fragmented red cells (Fig. 22.19D) suggest hemolysis associated with physical trauma to the erythrocyte or with diseases affecting small blood vessels.

Bite cells are erythrocytes that look as if a semicircular bite has been taken from one edge. Hemighosts are red cells that look as if the Hb has shifted to one side of the cell, leaving the other side clear. These hemighosts also are referred to as blister cells and may appear to contain a coagulum of Hb that has separated from the membrane (Fig. 22.19E). These cells are seen in patients with oxidant-induced injury, such as in G6PD deficiency.

Autoagglutination may be apparent in blood smears (Fig. 22.19F) or may even be visible to the naked eye when the blood is allowed to flow along the side of a glass container. The phenomenon is particularly characteristic of immunohemolytic disease caused by cold agglutinins. Autoagglutination must be distinguished from rouleau formation, a manifestation of multiple myeloma and related diseases and the phenomenon responsible for accelerated rates of erythrocyte sedimentation.

Direct Antiglobulin Test

The test used for detection of immunohemolytic anemia is the direct antiglobulin or Coombs test (see discussion in Chapter 29). Positive test results indicate that the red cells are coated with IgG or complement components, especially C3. However, 2% to 5% of patients with immunohemolytic disease have negative test results because the amount of globulin on the cell surface is below the detection limits.¹⁷⁶ Occasionally, patients have weakly positive test results and no clinical evidence of hemolysis. Positive tests are found in as many as 34% of patients with AIDS without other evidence of immunohemolytic disease.¹⁷⁷

Osmotic Fragility Test

The osmotic fragility test is a measure of the resistance of erythrocytes to hemolysis by osmotic stress. The test consists of exposing red cells to decreasing strengths of hypotonic saline solutions and measuring the degree of hemolysis. A symmetric, sigmoidal curve is obtained in most subjects (Fig. 22.20). Increased fragility is indicated by a shift of the curve to the left, whereas osmotic resistance (reduced fragility) is signified by a rightward shift of the curve. Increased osmotic fragility is observed in conditions associated with spherocytosis. With prior incubation of sterile blood for 24 hours,¹⁷⁸ the increased osmotic fragility of spherocytes is greatly accentuated, whereas normal cells become only slightly more fragile. The osmotic fragility of unincubated blood may be normal in some patients with hereditary spherocytosis, and for this reason, the test should be performed on incubated samples. Determination of osmotic fragility is of value chiefly in confirming important morphologic findings, especially the presence of spherocytes. In most cases, however, the osmotic fragility test does not provide information that was not already available from an expert examination of a well-prepared,

stained blood smear. Osmotic gradient ektacytometry is more sensitive and specific than the osmotic fragility test for the diagnosis of hereditary spherocytosis, but is not widely available.¹⁵⁹

Tests for Hemolytic Disorders Associated with Heinz Body Formation

In certain disorders, the hemolytic process involves precipitation of Hb, with the formation of inclusions known as Heinz bodies. These inclusions are rapidly removed by the spleen. Heinz body formation is the principal mechanism of hemolysis in G6PD deficiency and related disorders (Chapter 28), in unstable Hb disease (Chapter 35), in the thalassemias (Chapter 34), and in certain kinds of chemical injury (Chapter 32). Heinz bodies are not observed when ordinary staining procedures are used, but require the use of special supravital stains (Fig. 22.21). Cells containing these inclusions may be found in the blood during an acute hemolytic episode in subjects with G6PD deficiency and also in splenectomized individuals with unstable Hb disease. When the spleen is intact, however, the inclusions are

P.613

removed with such efficiency that the inclusion-containing cells often are not seen.

FIGURE 22.20. Osmotic fragility (as manifested by percent hemolysis) of normal and hereditary spherocytosis (HS) erythrocytes after incubation in salt solutions of varying tonicity. In fresh HS erythrocytes, note the “tail” of cells with increased sensitivity as a result of splenic conditioning (left). In the incubated red blood cell (RBC), note that the entire HS population of RBCs is more osmotically sensitive (right). From Glader BE, Naumovski L. Hereditary red blood cell disorders. Diagnostic Strategy for the Patient with Hemolytic Anemia

Establishing the Presence of Hemolytic Anemia

The most common manifestations of chronic hemolytic anemia include anemia and reticulocytosis, often associated with various signs of excessive blood destruction. In contrast, an acute hemolytic anemia initially may not be accompanied by signs of accelerated red cell production. Such a diagnosis may be suspected because of the abrupt onset of hemoglobinuria or other signs of intravascular hemolysis or because of a rapid fall in blood Hb concentration from previously stable levels.

Conditions Sometimes Mistaken for Hemolytic Anemia

Anemias associated with acute hemorrhage and those with partially treated deficiency states are characterized by transient anemia and reticulocytosis (Table 22.14). They usually can be distinguished from hemolytic disease by the absence of icterus and by a rising Hct on subsequent determinations.

FIGURE 22.21. Heinz bodies (seen with brilliant cresyl blue supravital stains of blood) during hemolytic episodes in patient with glucose-6-phosphate dehydrogenase (G6PD) deficiency. From Pierira I, George TI, Arber DA in Atlas of peripheral blood. Philadelphia, PA: Lippincott Williams & Wilkins, 2012.

Anemias caused by ineffective erythropoiesis often are accompanied by jaundice and erythroid marrow hyperplasia; however, the reticulocyte count usually is not increased.

A particularly confusing situation may arise after occult hemorrhage into the retroperitoneal space or other tissue compartments; anemia develops rapidly, and reticulocytosis follows. Furthermore, indirect hyperbilirubinemia may occur as the result of reabsorption of the products of Hb breakdown at the site of hemorrhage. Thus, the picture of hemolytic anemia may be simulated in several ways. Diagnosis depends on detecting signs of the hemorrhage itself or the disease process leading to it. If occult hemorrhage is suspected, serial observations usually clarify the situation; once the hemorrhage ceases, the Hct, reticulocyte count, and bilirubin values return to normal.

In individuals with acholuric jaundice but without anemia, the differential diagnosis lies between a compensated hemolytic state and Gilbert syndrome or other disorders of bilirubin catabolism. Reticulocytosis or morphologic abnormalities of erythrocytes are typical findings in the former. In mild compensated hemolytic disease, however, one cannot always be certain that the hematologic values will be abnormal. Fasting induces an exaggerated increase in bilirubin levels in patients with Gilbert syndrome,¹⁷⁹ and this phenomenon may be useful in distinguishing Gilbert syndrome from hemolytic anemia.

Anemia associated with marrow invasion may be accompanied by erythroblastosis and bizarre abnormalities of erythrocyte shape. Mild reticulocytosis may develop because of premature release of cells from the marrow. Usually, however, patients do not have jaundice, and evidence of the invasive disease may be detected by examination of the bone marrow.

Determining the Specific Cause of Hemolysis

Information from the medical history and physical examination, careful review of the CBC and peripheral blood smear, and results from the direct antiglobulin test, taken together, form the basis of the initial diagnosis assessment of hemolysis. From these data, five groups of patients can be distinguished.

- Those patients in whom the diagnosis is clear because of medical history such as obvious exposure to infectious, chemical, or physical agents. Some infections, such as malaria, can cause hemolysis directly, whereas in other cases it is more indirect, associated with an underlying G6PD deficiency or an unstable Hb, such as Hb H.

TABLE 22.14 CONDITIONS SOMETIMES MISTAKEN FOR HEMOLYTIC ANEMIA

Associated with anemia and reticulocytosis

Hemorrhage

Recovery from iron, folate, or vitamin B₁₂ deficiency

Recovery from marrow failure

Associated with jaundice and anemia

Ineffective erythropoiesis (intramedullary hemolysis)

Bleeding into a body cavity or tissue

Associated with jaundice without anemia

Defective bilirubin conjugation

Crigler-Najjar syndrome

Gilbert syndrome

Marrow invasion (myelofibrosis, metastatic disease)

Myoglobinuria

P.614

- Those patients with a positive direct antiglobulin test. Such individuals may be presumed to have immunohemolytic anemia. The subsequent investigation requires a search for an underlying disease as well as a serologic study of the nature of the antibody.
- Those patients with antiglobulin-negative, spherocytic hemolytic anemia. Such patients probably have hereditary spherocytosis. It is appropriate to confirm the presence of spherocytes by the osmotic fragility test and also to attempt to establish the familial nature of the illness by studying family members. Immunohemolytic anemia may be associated with spherocytosis and is occasionally associated with a negative antiglobulin reaction. Exposure to chemical or infectious agents producing spherocytosis may not always be easy to establish.
- Those patients with other specific morphologic abnormalities of erythrocytes. The significance of various types of abnormally shaped red cells was discussed previously. Some poikilocytes, such as elliptocytes and sickle cells, are virtually pathognomonic findings.
- Those with no specific morphologic abnormalities and a negative reaction to the antiglobulin test. These patients warrant a battery of screening tests, including Hb electrophoresis, the heat denaturation test for unstable Hb disease, tests for common red cell enzymes such as G6PD and pyruvate kinase, and a screening test for paroxysmal nocturnal hemoglobinuria.

If all of these procedures yield normal results, making the diagnosis is likely to be difficult. Possibilities include one of the rarer erythrocyte enzyme deficiencies or an unusual variant of congenital dyserythropoietic anemia. These entities can be established only by using specific assays and, soon to be available, genomic sequencing for enzyme and cytoskeletal protein gene mutations.

APPROACH TO ACUTE POSTHEMORRHAGIC ANEMIA

When blood loss occurs in small amounts over a prolonged period, no anemia develops until iron stores are depleted. In such circumstances, the hematologic findings are those of iron deficiency anemia. On the other hand, when larger amounts of blood are lost over shorter periods of time, anemia may develop, although iron stores remain adequate. This latter condition is called acute posthemorrhagic anemia.

The patient may be asymptomatic and appear to be in shock, or the entire situation might be confused with an acute hemolytic process.

The physiologic changes that occur with acute blood loss in otherwise healthy individuals are summarized in Table 22.15. The immediate effects of acute hemorrhage are primarily cardiovascular. The plasma volume and red cell mass are reduced in proportional amounts; consequently, no decrease is observed in the Hct.^{180,181} Because of the time required for extracellular fluid to restore the blood volume, the amount of blood loss tends to be underestimated by the degree of anemia, especially early in the disease course. The platelet count increases, often reaching levels above normal within 1 hour, and values greater than 1 million platelets/ul can be observed. There also is a neutrophilic leukocytosis over 2 to 5 hours. Typically, the leukocyte count is 10 to 20 × 10⁴/μL. The leukocytosis is explained in part by the effect of epinephrine on granulocyte demargination and release from the marrow granulocyte reserve.

When first detected, the anemia following acute hemorrhage is normocytic with few signs of erythrocyte regeneration. The Hct or Hb may not reach the minimum value until 3 days or more after the hemorrhage ceases.

Some increase in the number of reticulocytes is usually perceptible within 3 to 5 days, and maximal values are reached at 6 to 11 days.¹⁸² The degree of reticulocytosis is related to the magnitude of hemorrhage, but rarely exceeds 15%. Other signs of erythrocyte regeneration include polychromatophilia and macrocytosis, and the MCV may transiently increase. If the patient is seen for the first time during this stage, the findings may be mistaken for those of hemolytic anemia; however, signs of increased bilirubin production are conspicuously absent, unless there has been bleeding into a body cavity or tissue space.

TABLE 22.15 CLINICAL FEATURES OF ACUTE HEMORRHAGE IN HEALTHY YOUNG ADULTS

Volume of Blood Loss (ml)	Blood Volume (%)	Symptoms
500-1,000	10-20	Few if any symptoms
1,000-1,500	20-30	Asymptomatic while at rest in a recumbent position; light-headedness and hypotension when upright; tachycardia
1,500-2,000	30-40	Symptoms present when subject is recumbent; thirst, shortness of breath, clouding or loss of consciousness; blood pressure, cardiac output, venous pressure decrease; pulse usually becomes rapid; extremities become cold, clammy, and pale
2,000-2,500	40-50	Lactic acidosis, shock; irreversible shock, death

An external hemorrhage of a magnitude sufficient to cause significant anemia is usually evident. Similarly, substantial bleeding from the gastrointestinal or female reproductive tract is likely to be a dramatic event with readily detected signs and symptoms. Internal bleeding, as from a ruptured aneurysm, may be less apparent but should be suspected when there is the abrupt onset of shock or unexplained hypotension and tachycardia. Often, these manifestations are accompanied by symptoms referable to the site of bleeding. Hemorrhage into the retroperitoneal space, a body cavity, or a cyst sometimes presents a diagnostic problem. There may be a rapid onset of anemia accompanied by hyperbilirubinemia arising from the breakdown and absorption of RBCs. Under such circumstances, the picture may be transiently confused with acute hemolytic anemia. In all cases, the onset of a sudden, unexplained anemia should lead to the suspicion of covert bleeding. The suspicion is strengthened if signs of regeneration, such as reticulocytosis, appear and no evidence of excessive blood destruction is found.

Elective surgery is a special circumstance in which hemorrhage is predictable. Surgical mortality is clearly increased when patients are severely anemic. In Jehovah's Witness patients who refuse transfusion, surgical mortality is approximately 60% at Hb values less than 6 g/dl and more than 30% at values between 6 and 8 g/dl.¹⁸³ At values greater than 8 g/dl, no increased mortality is observed. An older guideline requiring preoperative transfusion if the Hb is less than 10 g/dl has been replaced by a lower trigger point, 7 g/dl, in otherwise healthy, younger patients.^{184,185} Surgeons and anesthesiologists use several techniques to avoid the need for allogeneic transfusions.¹⁸⁶ These techniques include the use of autotransfusion of cells harvested during surgery¹⁸⁷ and preoperative harvesting of autologous blood.^{188,189} The preoperative or postoperative use of erythropoietin injection or iron medication has proved disappointing^{190,191} but may have a role with severely anemic Jehovah's Witness patients.¹⁹²

Chapter 23

Iron Deficiency and Related Disorders

Lawrence T. Goodnough

Elizabeta Nemeth

Iron deficiency has been recognized since medieval times. Chlorosis, a term derived from the Greek word meaning green, was applied by Varandaeus to a disorder that was later described in 1554 as “De morbo virgineo.”¹ The disease became well known as the “green-sickness,” due to a greenish pallor occurring almost exclusively in teenaged girls.² It was depicted in paintings by the Dutch masters and was alluded to by Shakespeare. Other clinical features were breathlessness, palpitations, slight ankle edema, and gastrointestinal complaints. Emotional disturbances, depression, irritability, and moodiness were common.

Chlorosis became especially common in the last decade of the 19th century and then declined in incidence. Today, most believe that chlorosis resulted from a combination of factors affecting adolescent girls: the demands of growth and the onset of menses, an inadequate diet, and a legacy of poor iron stores from early childhood. In the 1830s, anemia, hypochromia, and lack of iron in the blood were linked to this disorder.³ In 1832, Pierre Blaud described the response of chlorosis to his deservedly famous pills (ferrous sulfate plus potassium carbonate). Many observers, including Niemeyer and Osler, confirmed his findings.⁴ Ferrous sulfate remains a cornerstone of modern treatment of iron deficiency.

In the late 1920s and early 1930s, a distinct hypochromic anemia was described. Like chlorosis, chronic hypochromic anemia chiefly affected women. It differed from chlorosis in that it was detected later in life, especially in the fourth and fifth decades.⁵ Other distinguishing clinical features were epithelial changes involving the tongue and nails and achlorhydria. The anemia most often affected women with poor diets, multiple pregnancies, or menstrual irregularities. Today, menstruating women continue to be among the most likely individuals to develop iron deficiency, along with young children whose growth outstrips their iron supply. An understanding of normal iron physiology is essential to best appreciate the pathophysiology of iron deficiency anemia.

TABLE 23.1 IMPORTANT FE-CONTAINING COMPOUNDS IN THE HUMAN

Protein	Function	Fe Oxidation State	Amount (g)	Percent of Total
Hemoglobin	Erythrocyte O ₂ transport	2 (heme)	2.600	65.0
Myoglobin	Muscle O ₂ storage	2 (heme)	0.130	6.0
Transferrin	Plasma Fe transport	3	0.003	0.1
Ferritin	Intracellular Fe storage	3	0.520	13.0
Hemosiderin	Intracellular Fe storage	3	0.480	12.0
Others (enzymes)			0.150	3.9

NORMAL IRON PHYSIOLOGY

Total Body Iron

Iron endowment varies with age and sex. Full-term infants begin life with approximately 75 mg/kg body weight of iron, primarily acquired from their mothers during the third trimester of gestation. These abundant stores are rapidly depleted over the first few months of life, and most young children have tenuous iron balance, as their intake must keep pace with rapid growth. Requirements decrease after adolescence, and men have a small gradual increase in iron stores throughout life. The body iron content of normal adult men is 50 mg/kg body weight or greater. In contrast, postpubertal women have increased losses of iron due to menstruation, pregnancy, and childbirth, resulting in a body iron endowment averaging 35 mg/kg. After menopause, women accumulate iron linearly in parallel with adult men.

Most of the body iron is found in heme-containing oxygen transport and storage proteins, including hemoglobin and myoglobin (Table 23.1). Smaller amounts are incorporated into enzymes with active sites containing heme or iron-sulfur clusters, including enzymes of electron transport chain, peroxidases, catalases, and ribonucleotide reductase. Most nonheme iron (approximately 1 g in adult men) is stored as ferritin or hemosiderin in macrophages

P.618

and hepatocytes. Only a tiny fraction of iron (~0.1%) is in transit in the plasma, bound to the carrier protein, transferrin.

Iron Balance

Iron is not actively excreted from the body; it is eliminated only through the loss of epithelial cells from the gastrointestinal tract, epidermal cells of the skin, and, in menstruating women, red blood cells. On the basis of long-term studies of body iron turnover, the total average daily loss of iron has been estimated at ~1 to 2 mg in normal adult men and nonmenstruating women.⁶ Although iron is a physiologic component of sweat, only a tiny amount of iron (22.5 µg/L) is lost by this route.⁷ Urinary iron excretion amounts to <0.05 mg/day and is largely accounted for by sloughed cells.

Menstruating women lose an additional, highly variable amount over each menstrual cycle, from 0.006 (average) to more than 0.025 mg/kg/day.⁸

These iron losses are normally balanced by an equivalent amount of iron absorbed from the diet (1 to 2 mg/day). The bioavailability of iron in the U.S. diet has been estimated to be ~16.6%, but only a fraction of dietary iron is absorbed and the amount of bioavailable iron is lower in many parts of the world. Fractional absorption of dietary iron can increase up to three- to fivefold (3 to 5 mg/day) if iron stores are depleted. Thus, iron balance is primarily, if not exclusively, achieved by control of absorption rather than by control of excretion.

Intestinal Absorption

Iron is absorbed in the duodenum, and humans and other omnivorous mammals have at least two distinct pathways for iron absorption: one for uptake of heme iron and another for ferrous (Fe^{2+}) iron. Heme iron is derived from hemoglobin, myoglobin, and other heme proteins in foods of animal origin, representing approximately 10% to 15% of iron content in the typical Western diet,⁹ although heme-derived iron accounts for 2/3 of absorbed iron in meat-eating humans. Exposure to acid and proteases present in gastric juices frees the heme from its apoprotein. Heme is taken up by mucosal cells, but the specific receptor is still unknown.¹⁰ Once heme iron has entered the cell, the porphyrin ring is enzymatically cleaved by heme oxygenase.¹¹ The liberated iron then probably follows the same pathways as those used by nonheme iron. A small proportion of the heme iron may pass into the plasma intact via heme exporter protein FLVCR (feline leukemia virus, subgroup C receptor),¹² which transfers heme onto a heme-binding protein, hemopexin.¹³ Absorption of heme iron is relatively unaffected by the overall composition of the diet.⁹

Dietary nonheme iron is largely in the form of ferric hydroxide or loosely bound to organic molecules such as phytates, oxalate, sugars, citrate, lactate, and amino acids. Low gastric pH is thought to be important for the solubility of inorganic iron. Dietary constituents may also have profound effects on the absorption of nonheme iron, making the bioavailability of food iron highly variable.⁹ Ascorbate, animal tissues, keto sugars, organic acids, and amino acids enhance inorganic iron absorption, whereas phytates, polyphenols, and calcium inhibit it.¹⁴ Depending on various combinations of enhancing and inhibitory factors, dietary iron assimilation can vary as much as tenfold.

Molecular Mechanisms of Iron Absorption

Absorption of nonheme iron occurs in the duodenum, where ferrous iron is imported into enterocytes by divalent metal ion transporter 1 (DMT1, also known as Nramp2, DCT1, SLC11A2).^{15,16} DMT1 is a protein with 12 predicted transmembrane segments, which is expressed on the apical surface of absorptive enterocytes. Levels of DMT1 are markedly increased in iron-deficient animals¹⁷ and in some animals with increased intestinal iron absorption resulting from other causes.¹⁸ In addition to iron, DMT1 may also contribute to the absorption of other nutritionally important metals (e.g., Mn^{2+}).¹⁹ Evidence in vitro demonstrates that DMT1 is a proton-coupled symporter.^{15,20} The Na^+/H^+ exchanger in the duodenum is thought to create the "acid microclimate" that provides the proton electrochemical gradient as the driving force for iron uptake.¹⁶

DMT1 does not transport the Fe^{3+} form of iron, but as discussed previously, most dietary nonheme iron arrives at the brush border as Fe^{3+} ion. A duodenal cytochrome b-like ferrireductase enzyme, Dcytb (also called CYBRD1), likely reduces dietary Fe^{3+} to make it a substrate for transport by DMT1.²¹ Dcytb is induced in response to stimuli that increase iron absorption; however, since knockout mice appear to have normal metabolism, Dcytb may not be the only ferrireductase enzyme involved in absorption of nonheme iron.²²

A variable fraction of iron taken into the mucosal cell is delivered to the plasma. The remainder is used by the cell or incorporated into ferritin,²³ an intracellular iron storage protein discussed in a later section. Iron retained in mucosal ferritin is not absorbed, rather, it is lost from the body when the senescent mucosal cells are sloughed into the intestine at the end of their 3- to 4-day lifespan (10^{11} cells/day).²⁴

Iron not stored in the absorptive enterocytes is transferred across the basolateral membrane of the cell to the lamina propria and ultimately to the plasma. This is accomplished, at least in part, by the iron exporter ferroportin (also known as FPN1, IREG1, MTP1, SLC40A1), a multi-transmembrane segment protein expressed on the basolateral surface of enterocytes.^{25,26,27,28} Ferroportin is also expressed in other tissues involved in handling large iron fluxes including macrophages recycling iron from old red blood cells, hepatocytes storing iron, and placental trophoblast delivering iron from mother to fetus. Complete ablation of ferroportin in mice, including extraembryonic tissues, resulted in embryonic death,²⁸ whereas selective inactivation that preserved placental ferroportin expression resulted in live births, demonstrating the essential function of ferroportin in materno-fetal iron transfer. Ferroportin is also essential for systemic iron homeostasis as inactivation of ferroportin in all tissues in mice other than placenta led to the development of severe

anemia resembling iron deficiency, and stemmed from the inability to mobilize iron from enterocytes, macrophages, and hepatocytes.²⁸

Similar to apical iron uptake, basolateral iron efflux is aided by an enzyme that changes the oxidation state of iron. Ferroportin exports Fe^{2+} and this iron must be oxidized to its Fe^{3+} form to bind to transferrin. A membrane-bound multicopper oxidase, hephaestin, has been implicated in this process.²⁹ Hephaestin closely resembles ceruloplasmin,³⁰ which has been shown to be involved in efflux of iron from hepatocytes and macrophages. Mice carrying a large deletion in the X-chromosomal hephaestin gene²⁹ have impaired placental iron transfer and decreased intestinal iron absorption.^{31,32} Their iron deficiency results in anemia during the neonatal period, but affected animals generally recover and show only subtle evidence of iron deficiency as adults. The simplest interpretation is that hephaestin is important in placental iron transport but dispensable for intestinal iron uptake. The functional relationship between hephaestin and ferroportin has not yet been defined in detail. A model incorporating current knowledge of nonheme iron transport is shown in Figure 23.1.

Regulation of Iron Absorption

Because the total body iron content is largely determined by the efficiency of absorption of iron, the regulation of absorption has been of great interest for many years. Both systemic mechanisms and local mechanisms within enterocytes (discussed later in the chapter) regulate dietary iron uptake. The systemic signals that are of prime importance in determining absorptive rate are the

P.619

amount of storage iron in the body and the erythropoietic activity. When storage iron is depleted, iron absorption is increased; when it is excessive, iron absorption is decreased. This has been termed the stores regulator.³³ The erythroid regulator³³ modulates iron absorption in response to erythropoietic need and mediates an increase in intestinal iron absorption when the red cell production rate is increased. This is observed in effective as well as in ineffective erythropoiesis when erythroid precursors are destroyed relatively close to their site of origin in the bone marrow (as seen in thalassemia syndromes, congenital dyserythropoietic anemias, and sideroblastic anemias). It is now known that the hormone hepcidin functions as both the stores and erythroid regulator.

FIGURE 23.1. Nonheme iron absorption in the intestine. The figure shows a drawing of an absorptive enterocyte from the proximal duodenum. The apical brush border is at the top. Dietary nonheme iron enters the gut as the ferric (Fe^{3+}) ion and is converted to the ferrous (Fe^{2+}) ion by a surface reductase activity, probably mediated by the duodenal cytochrome b-like (DCYTB) protein. The Fe^{2+} iron enters the cell through the action of divalent metal ion transporter 1 (DMT1). Within

the cell, some iron is stored, and some is transported across the basolateral membrane. Ferroportin is believed to function as a basolateral Fe^{2+} iron transporter. Hephaestin, a ferroxidase, facilitates basolateral iron export, possibly by oxidizing the iron as it exits the cell to the Fe^{3+} form to bind to plasma apotransferrin.

Hepcidin and Systemic Regulation of Iron Metabolism

Hormone hepcidin has emerged as the key systemic regulator of iron homeostasis. Hepcidin is a small peptide of 25 amino acids, produced in the liver, secreted into the plasma, and excreted through the kidneys.^{34,35} Hepcidin is structurally similar to antimicrobial peptides involved in innate immunity, but its main role is to inhibit iron fluxes into plasma.³⁶ Mutations in the human hepcidin gene cause severe, early-onset iron overload.³⁷ Mice lacking hepcidin also develop severe iron overload,³⁸ whereas transgenic mice constitutively expressing hepcidin have severe iron deficiency anemia.³⁹ A single injection of synthetic hepcidin into mice exerts a prolonged hypoferremic effect.⁴⁰ All of these effects can be explained by the biologic activity of hepcidin. Hepcidin binds to the iron exporter ferroportin, causing ferroportin endocytosis and lysosomal degradation,⁴¹ and resulting in cessation of cellular iron export. Thus, hepcidin directly and coordinately controls the entry of iron into the plasma from ferroportin-expressing cells, including absorptive cells of the intestine and tissue macrophages (Fig. 23.2).

Alterations in hepcidin production lead to changes in iron absorption and recycling. Multiple signals are known to regulate hepcidin expression, including iron, erythropoiesis, inflammation, and growth factors.

As with other hormones that are feedback regulated by the substances whose concentration they control, hepcidin expression is controlled by iron. When iron is deficient, hepatocytes produce less hepcidin, allowing more iron to enter plasma. When iron is abundant, hepcidin production increases, limiting further iron absorption and release from stores. In human volunteers ingesting a single dose of oral iron, hepcidin concentrations in urine increased within several hours and were proportional to the increase in transferrin saturation.⁴² Serum hepcidin concentrations in healthy subjects also correlate with body iron stores as reflected by serum ferritin.⁴³ The specific forms of iron that increase hepcidin synthesis may include diferric plasma transferrin and intracellular iron in hepatocytes, and the transduction pathways that regulate hepcidin synthesis in response to these iron forms are just now being elucidated.

The two transferrin receptors TfR1 and TfR2, and HFE, an MHC class I-like membrane protein, may serve as holotransferrin sensors.³⁶ HFE can interact with both transferrin receptors, but this interaction is modulated by holotransferrin concentrations. Because HFE and holotransferrin binding sites on TfR1 overlap, increasing concentrations of holotransferrin result in displacement of HFE from TfR1, and free HFE then interacts with

P.620

TfR2.^{44,45} TfR2 protein is further stabilized by binding of holotransferrin.⁴⁶ The holotransferrin/HFE/TfR2 complex then stimulates hepcidin expression through an incompletely understood pathway, possibly by potentiating BMP pathway signaling. HFE, however, may also regulate hepcidin expression without complexing with TfR2.⁴⁷ The role of HFE or TfR2 in hepcidin regulation by iron is supported by genetic evidence: HFE and TfR2 mutations in humans or mice cause hepcidin deficiency and an adult form of hemochromatosis.³⁶

FIGURE 23.2. Regulation of systemic iron homeostasis by hepcidin. Hepcidin controls the entry of iron into plasma by causing degradation of its receptor, the iron exporter ferroportin. The major iron flows that are regulated by hepcidin-ferroportin interactions include the release of iron from macrophages that recycle iron in the spleen and the liver, dietary iron absorption in the duodenum, and, at least in part, the release of iron from storage in hepatocytes. The feedback stimulation of hepcidin by plasma holotransferrin and iron stores ensures that extracellular iron concentration and iron stores stay within normal limits. Hepcidin synthesis is suppressed by erythropoietic activity, ensuring a sufficient supply of iron to the bone marrow when demand for hemoglobin synthesis is high. During inflammation, hepcidin production is stimulated and iron entry into plasma is inhibited, causing the hypoferremia and anemia of inflammation. From Ganz T. Molecular control of iron transport. *J Am Soc Nephrol* 2007;18(2):394-400.

The BMP pathway with its canonical signaling via Smad proteins has a central role in the regulation of hepcidin transcription. BMP receptors are tetramers of serine/threonine kinase receptors, with two type I and two type II subunits. Recent data indicate that type I subunits Alk2 and Alk3 and type II subunit ActRIIA and BMPRII are specific BMP receptors involved in iron regulation.^{48,49} In the liver, BMP pathway signaling to hepcidin is modulated by a coreceptor hemojuvelin and, at least in mice, by the ligand BMP6.^{50,51,52} Loss of hemojuvelin or BMP6 in mice decreases hepcidin expression and impairs hepcidin response to acute or chronic iron loading.⁵³ In humans, hemojuvelin mutations result in severe hepcidin deficiency and cause juvenile hemochromatosis.⁵⁴ No pathogenic human mutations in BMP6 have yet been identified. It remains to be clarified how BMP receptors and hemojuvelin interact with iron-sensing molecules that regulate hepcidin expression.

Two other membrane proteins, a serine protease matriptase-2 (MT-2, also called transmembrane protease serine 6, Tmprss6) and the receptor neogenin also influence hepcidin synthesis, likely by modulating hemojuvelin concentration on the cell membrane.^{55,56} Whether these molecules are involved in iron sensing is unclear, but the concentration of hepatic MT-2 is acutely increased by iron deficiency.⁵⁷ Mutations in MT-2 in humans and in mice lead to increased hepcidin expression and development of iron-restricted anemia, discussed later in this chapter.

As already mentioned, hepcidin synthesis also increases in response to stored intracellular iron in hepatocytes but the underlying mechanism is yet unclear. Hepatic BMP6 mRNA increases in response to iron loading, suggesting that BMP6 may be a mediator of intracellular iron signal.⁵⁸ However, hepcidin increase after chronic iron loading is still observed in BMP6-deficient mice,⁵³ indicating that additional pathways must play a role in hepcidin regulation by intracellular iron. Figure 23.3 summarizes our current understanding of the molecular mechanisms involved in hepcidin regulation by iron.

Hepcidin synthesis, and consequently absorption of iron and its availability for erythropoiesis, is also regulated by erythropoiesis itself. Increased erythropoietic activity due to bleeding, hemolysis, or administration of erythropoietin in humans or mice causes hepcidin suppression.^{59,60,61} Very low hepcidin concentrations are observed in patients with absolute iron deficiency anemia, or anemias with high erythropoietic activity.⁴³ In turn, low hepcidin allows increased absorption of dietary iron and release of iron from stores, thus increasing iron supply to the bone marrow for hemoglobin synthesis. The mechanisms by which erythropoiesis regulates hepcidin production are not well understood, but it is thought that erythroid precursors in the bone marrow secrete a factor which exerts its effect on hepatocytes and causes hepcidin suppression.⁶⁰

The suppressive effect of erythropoiesis on hepcidin is particularly prominent in diseases with ineffective erythropoiesis such as β -thalassemia,^{62,63} where erythrocyte precursors massively expand but undergo apoptosis rather than mature into erythrocytes. The severe suppression of hepcidin, particularly in untransfused β -thalassemia, leads to increased iron absorption and the development of lethal iron overload. Growth differentiation factor GDF-15, a BMP-related protein released by erythroid precursors during cellular stress or apoptosis, may contribute to hepcidin suppression in anemias with expanded but ineffective erythropoiesis.⁶⁴ However, GDF-15 does not seem to be involved in homeostatic hepcidin suppression by effective erythropoiesis.⁶⁵

FIGURE 23.3. Molecular mechanisms of hepcidin regulation. Hepcidin is regulated by iron, inflammation, and erythropoiesis, but molecular details for the latter are not understood. In the iron-regulated pathway, extracellular iron in the form of holotransferrin (HoloTf) is sensed by the two transferrin receptors (Tfr1 and Tfr2). Binding of HoloTf to its receptors promotes HFE interaction with Tfr2 instead of Tfr1, and HFE/Tfr2 complex then sensitizes the BMP receptor to its ligands such as BMP6. Hemojuvelin (HJV), a membrane-linked BMP pathway coreceptor, also potentiates the BMP receptor activation. Once activated, BMP receptors initiate SMAD signaling which increases hepcidin transcription. This pathway is also modulated by matriptase-2 (MT-2) protease which cleaves hemojuvelin, and by neogenin which may augment or stabilize membrane hemojuvelin. Intracellular iron in hepatocytes also increases hepcidin expression, possibly

through a mechanism that enhances BMP6 production, eventually leading to activation of the BMP receptor. Alternative ligands with BMP6-like activity must exist because mice that lack BMP6 still increase hepcidin mRNA in response to iron stores. Hepcidin transcription is prominently increased by inflammation, predominantly through the activity of IL-6, its receptor, and its canonical JAK-STAT3 pathway. From Ganz T, Nemeth E. Hepcidin and iron homeostasis. *Biochim Biophys Acta*. 2012 Jan 26 [Epub].

Hepcidin gene expression is induced in response to inflammatory cytokines,⁶⁶ accounting for iron sequestration in the anemia of inflammation (see Chapter 45).^{59,67} IL-6 signaling through the STAT-3 pathway seems to be a key regulator of hepcidin expression in inflammation.^{68,69} Apart from increased transcription, elevated hepcidin concentrations in circulation could result from impaired renal clearance of hepcidin. Because of its small size (2.7 kDa), hepcidin is filtered through the glomerular membrane and is then taken up and degraded in the proximal tubule. A fraction of the filtered hepcidin is excreted into urine, and urinary hepcidin concentrations are proportionate to plasma hepcidin levels in healthy subjects.⁴³ In chronic kidney diseases, however, hepcidin clearance is impaired,⁷⁰ contributing to the hormone accumulation in plasma.

Regulation of Iron Absorption by Intracellular Mechanisms

In addition to the regulation by systemic signals, iron absorption is subject to local regulation by intracellular mechanisms in duodenal enterocytes. At least two mechanisms have been described: one related to the enterocyte iron levels and the other to the hypoxia pathway.

Intracellular iron levels in enterocytes (and most other cells) are sensed by two iron-regulatory proteins (IRP1 and IRP2).⁷¹ When cytoplasmic iron is low, IRPs bind to iron-regulatory elements (IREs),⁷² stem-loop structures located in the 5' or 3' untranslated regions of different mRNAs. Binding of IRPs to 3' IREs stabilizes mRNAs by protecting them from endonucleolytic cleavage, resulting in increased protein synthesis. mRNAs which contain 3' IREs encode iron uptake proteins such as transferrin

P.621

receptor and a DMT1 isoform. In contrast, IRP binding to 5' IREs blocks translation of mRNA, by preventing the interaction with the cap-binding complex eIF4F and the small ribosomal subunit,⁷³ resulting in decreased protein synthesis. 5' IREs are present in ferritin mRNA and one of ferroportin transcripts. In iron-replete cells, neither IRP binds to IREs, resulting in greater degradation of 3' IRE-containing transcripts (e.g., Tfr1), and increased translation of 5' IRE-containing transcripts (e.g., ferritin), thus shifting the cellular phenotype from an iron-importing to an iron-storing one.

How does intracellular iron concentration modulate IRP binding to IREs? IRP1 contains a 4Fe•4S iron-sulfur cluster that, when saturated with iron, converts IRP1 to a cytosolic aconitase that catalyzes the conversion of citrate to isocitrate.^{74,75,76} In this enzyme form, IRP1 has low affinity for IREs in mRNAs. When iron-poor, IRP1 loses its aconitase activity and greatly increases its affinity for IREs. IRP2 is less abundant than IRP1 and does not have an identified enzyme function. Instead, intracellular iron levels control its degradation.^{77,78} In iron-replete cells, IRP2 is ubiquitinated by an iron-sensitive E3 ubiquitin ligase complex containing FBXL5 protein,^{79,80} and ubiquitinated IRP2 is degraded by proteasomes.

Targeted inactivation of the genes encoding murine IRPs has shed light on the roles of IRP1 and IRP2 in vivo. It is still not entirely clear why it is necessary to have two IRPs, but they may respond differently over the physiologically relevant range of oxygen tensions.⁸¹ There are no obvious consequences from the loss of IRP1 alone, and loss of IRP2 results in mildly abnormal iron homeostasis and iron-deficient erythropoiesis.^{82,83} Loss of both IRP proteins is incompatible with life.⁸⁴ Tissue-specific knockout of both IRPs in the intestine of mice confirmed their role in the regulation of iron transport in enterocytes. These animals had higher protein levels of ferroportin and ferritin and lower protein levels of DMT1. The knockout mice also had impaired intestinal function and died within 4 weeks of birth.⁸⁵

Even though IRPs regulate translation of ferroportin mRNA through its 5' IRE, duodenal ferroportin protein expression is paradoxically increased in iron deficiency. Recently, an alternative ferroportin transcript (FPN1B) was identified that could explain this phenomenon. FPN1B, which is highly expressed in the duodenum, lacks IRE and thus is not subject to translational repression by IRPs when intracellular levels are low.⁸⁶ This ensures that the transfer of iron from absorptive enterocytes into plasma continues even when those cells are iron deficient.

Dcytb mRNA also does not contain an IRE but is strongly upregulated in iron-deficient duodenum,⁸⁷ indicating additional regulation of transcription of iron-related genes. Hypoxia-inducible factor (HIF) transcription factors may serve as important local regulators of intestinal iron absorption. Iron deficiency induced HIF signaling in duodenum of mice, and caused increased DcytB and DMT1 expression, and an increase in iron uptake.⁸⁸ Accordingly, targeted deletion of Hif-2α in

the intestine resulted in dramatic decrease in the expressions of DMT1-IRE and Dcytb mRNA.⁸⁹ In vitro studies further demonstrated that HIF-2 α directly binds to the promoters of DMT1 and Dcytb, activating their transcription. Thus, HIF-2 α appears to be one of the critical local regulators of iron absorption.

Iron Cycle

Most functional iron in the body is not derived from daily intestinal absorption (1 to 2 mg/day) but rather from recycling of iron (20 to 25 mg/day) from senescent erythrocytes and other cells (Fig. 23.4). The most important source and destination of recycled iron is the erythron. At the end of a 4-month lifespan, effete erythrocytes are engulfed by reticuloendothelial macrophages, which lyse the cells and degrade hemoglobin to liberate their iron. This process is poorly understood, but it appears to involve the action of heme oxygenase for enzymatic degradation of heme. Some of this iron may remain stored in macrophages as ferritin or hemosiderin, but most is delivered to the plasma, and the rate of iron export is determined by the hepcidin-ferroportin interaction. In plasma, iron becomes bound to transferrin, completing the cycle. A small amount of iron, probably <2 mg, leaves the plasma each day to enter hepatic parenchymal cells and other tissues. Here, the iron is stored or used for synthesis of cellular heme proteins, such as myoglobin and the cytochromes.

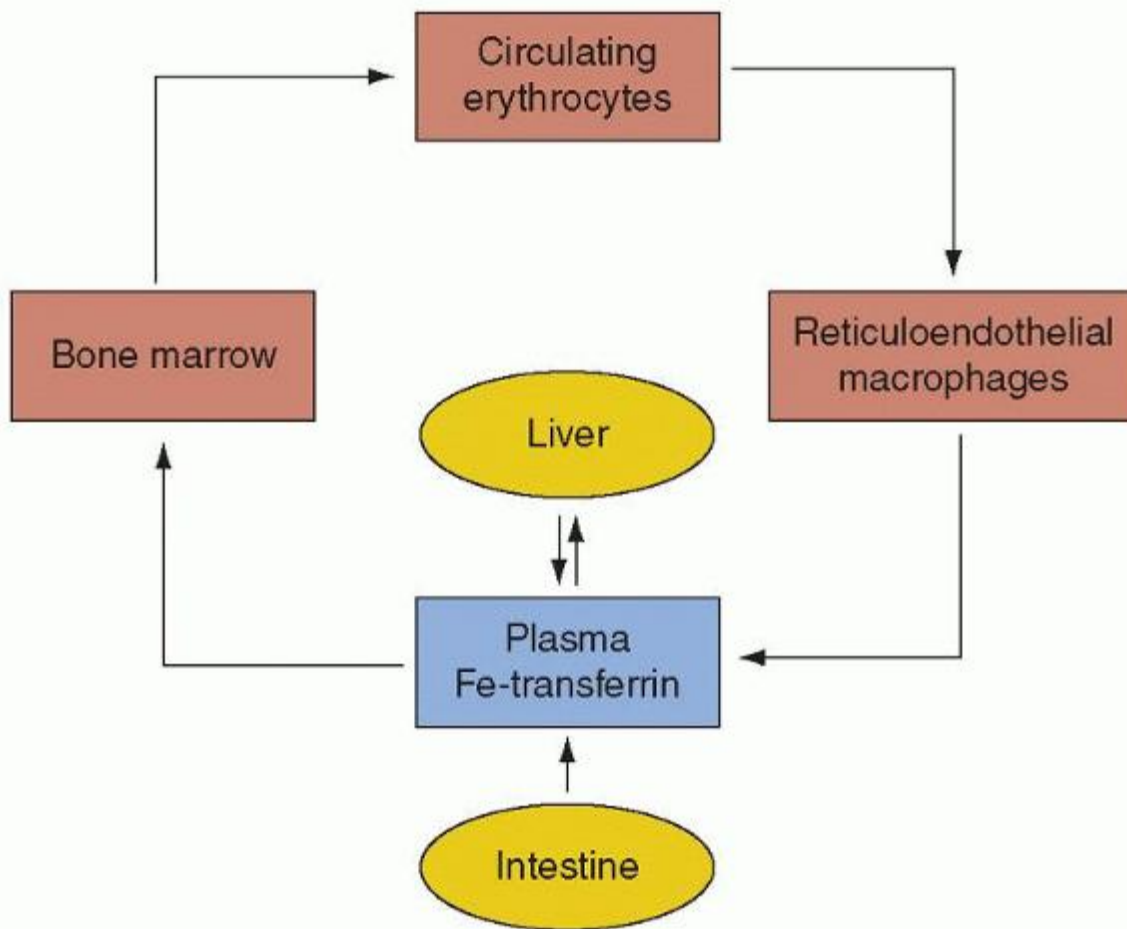

FIGURE 23.4. Iron cycle in humans. Iron (Fe) enters the body through the small intestine and travels in the plasma bound to transferrin. It is delivered to the erythroid bone marrow, where it is incorporated into hemoglobin and released into the circulation in mature erythrocytes. After a lifespan of approximately 120 days, erythrocytes are engulfed by macrophages in the reticuloendothelial system. There the Fe is extracted from hemoglobin and returned to plasma, where it becomes bound to transferrin, completing the cycle. Fe in excess of tissue needs is stored in the liver.

Plasma Transport

The plasma iron-binding protein, transferrin, is a glycoprotein with a molecular weight of approximately 80 kDa.⁹⁰ Transferrin is synthesized chiefly in the liver and actively secreted by hepatocytes, but lesser amounts are made in other tissues, including the central nervous system, the ovary, the testis, and helper T lymphocytes (T4⁺ subset). The rate of

synthesis shows an inverse relationship to iron in stores; when iron stores are depleted, more transferrin is synthesized, and when iron stores are overfilled, the level of transferrin decreases. Transferrin keeps iron nonreactive in the circulation and extravascular fluid, delivering it to cells bearing transferrin receptors.

Transferrin can be measured directly using immunologic techniques; and normal concentration in the plasma is approximately 2 to 3 g/L. Alternatively, transferrin is quantified in terms of the amount of iron it will bind, a measure called the total iron-binding capacity (TIBC; normal values for plasma iron and TIBC are given in Appendix A). In the average subject, the plasma iron concentration is $\sim 18 \mu\text{mol/L}$ (100 $\mu\text{g/dl}$), and the TIBC is $\sim 56 \mu\text{mol/L}$ (300 $\mu\text{g/dl}$). Thus, only about one third of the available transferrin binding sites are occupied, leaving a large capacity to deal with excess iron. Plasma iron concentration varies over the course of the day, with the highest values in the morning and the lowest in the evening. Levels of serum transferrin are more constant, and there is no apparent diurnal variation in TIBC. General practice has been to evaluate transferrin saturation using a first morning, fasting sample to standardize the results, but this may not be helpful.⁹¹

Transferrin has two homologous iron-binding domains, each of which binds an atom of trivalent (ferric) iron.⁹² The iron atoms

P.622

are incorporated one at a time and appear to bind randomly at either or both of the two sites. When binding is complete, the iron lies in a pocket formed by two polypeptide loops. One mole of anion, usually carbonate or bicarbonate, is taken up, and 3 moles of hydrogen ion are released for each mole of iron bound. There are functional differences between the two iron-binding sites,⁹³ but it is not clear that these have physiologic importance.

Under physiologic circumstances, ferric iron binds to transferrin with very high affinity, with an affinity constant of $\sim 1\text{-}6 \times 10^{22} \text{ M}^{-1}$. The affinity of iron-transferrin interaction is pH-dependent, decreasing as pH is lowered. Other transition metals, such as copper, chromium, manganese, gallium, aluminum, indium, and cobalt, can be bound by transferrin but with less affinity than iron.

Iron Delivery to Erythroid Precursors

The biologic importance of transferrin in erythropoiesis is illustrated by abnormalities observed in patients and mice with congenital atransferrinemia.^{94,95} and ^{96,97,98} When transferrin is severely deficient, red cells display the morphologic stigmata of iron deficiency. This occurs despite the fact that intestinal iron absorption is markedly increased in response to a perceived need for iron for erythropoiesis. Nonhematopoietic tissues avidly assimilate the non-transferrin-bound metal. Similarly, mutant mice lacking tissue receptors for transferrin die during embryonic development from severe anemia, apparently resulting from ineffective iron delivery to erythroid precursor cells.⁹⁸

Transferrin delivers its iron to developing normoblasts and other cells by binding to specific cell-surface receptors. The transferrin receptor (TfRC, TfR1) is a disulfide-linked homodimer of a glycoprotein with a single membrane-spanning segment and a short cytoplasmic segment. It is a type II membrane protein, with its N terminus located within the cell. The native molecular weight of TfR1 is $\sim 180 \text{ kDa}$. Each TfR1 homodimer can bind two transferrin molecules. Diferric transferrin is bound with higher affinity (association constant $2\text{-}7 \times 10^9 \text{ M}$) than monoferric transferrin. As a result, diferric transferrin has a competitive advantage in delivering iron to the erythroid precursors.⁹⁹ Apotransferrin has little affinity for the receptor at physiologic pH but considerable affinity at lower pH, an important factor in intracellular iron release.

Transferrin receptor 2 (TfR2), which shares $\sim 45\%$ homology with TfR1 in its large extracellular domain,¹⁰⁰ binds transferrin with lower affinity, and its role in cellular iron uptake is unclear. TfR2 is highly expressed in the liver and, as discussed earlier in this chapter, acts as an iron sensor that regulates hepcidin expression.³⁶ TfR2 is also expressed in erythroid precursor cells, where it interacts with the erythropoietin receptor and enhances the delivery of EpoR to cell surface.¹⁰¹

The role of TfR1 is relatively well understood. TfR1 numbers are modulated during erythroid cell maturation, reaching their peak in intermediate normoblasts. Very few TfR1 molecules are found on burst-forming-unit erythroid cells, and only slightly greater numbers are found on colony-forming-unit erythroid cells. However, by the early normoblast stage, approximately 300,000 receptors are found on each cell, increasing to 800,000 at the intermediate stages. The rate of iron uptake is directly related to the number of receptors. The number decreases as reticulocytes mature, and late in maturation, erythroid cells shed all remaining receptors by exocytosis and by proteolytic cleavage.¹⁰² The shed receptors (referred to as soluble transferrin receptors, sTfR) can be found in plasma in a concentration that correlates with the rate of erythropoiesis.¹⁰³ An increase in plasma sTfR is a sensitive indicator of erythroid mass and tissue iron deficiency.^{104,105}

After ligand and receptor interact, iron-loaded transferrin undergoes receptor-mediated endocytosis (Fig. 23.5).¹⁰⁶ Specialized endocytic vesicles form, which are acidified to a pH of 5 to 6 by the influx of protons. The low pH facilitates release of iron from transferrin and strengthens the apotransferrin-receptor interaction. Released iron is reduced by an endosomal ferrireductase, STEAP3,¹⁰⁷ and transferred to the cytosol by DMT1.¹⁰⁸ Because DMT1 must cotransport protons with iron atoms, vesicle acidification is also important for the function of this transporter. After the iron enters the cytosol, the protein components of the endosome return to the membrane surface, where neutral pH promotes the release of apotransferrin to the plasma. Both transferrin and TfR1 participate in multiple rounds of iron delivery.

FIGURE 23.5. Cellular uptake of iron-transferrin. Iron bound to plasma Tf (HoloTf) is delivered to the cell by binding to cell-surface transferrin receptor 1 (TfR). The ligand-receptor complex enters the cell through invagination of clathrin-coated pits to form specialized endosomes. The endosomes become acidified through the entry of protons, releasing Fe^{3+} iron from Tf and strengthening the apo-Tf/TfR complex at low pH. The released iron is reduced to Fe^{2+} by STEAP3 ferrireductase and exits the endosome through the divalent metal ion transporter 1 (DMT1) to go to sites of storage and use within the cell (ferritin, mitochondria). The apo-Tf/TfR complex then returns to the cell surface, where apo-Tf is released. Both Tf and TfR participate in multiple rounds of iron delivery.

Mutations in DMT1 can have profound effect on erythroid development. Although rare, DMT1 mutations have been described in several patients with congenital iron deficiency anemia.^{109,110,111} The patients suffer from severe microcytic, hypochromic anemia, due to the inability to transport iron out of Tf/TfR1 endocytic vesicles, thus preventing iron delivery for heme synthesis. Although DMT1 is also involved in duodenal iron absorption, most of these patients develop hepatic overload at a young age, suggesting that iron absorption is at least partially intact, probably due to dietary heme absorption. Blood transfusions to correct the anemia also contribute to patients' iron overload.

Once inside the cell, erythroid iron must be shuttled to the mitochondrion, where it will be incorporated into protoporphyrin IX by ferrochelatase, the final enzyme of heme biosynthesis. How iron that is exported from endosome

reaches the mitochondrion and is transported across the outer mitochondrial membrane is not well understood. Iron transport across the inner mitochondrial membrane seems to be mediated by mitoferrin-1, a transmembrane iron transporter.¹¹² Inactivation of the mitoferrin-1 gene in mice prevents red blood cell production, underscoring the importance of this protein in erythroid biology. An alternative mechanism for iron delivery from Tf/TfR endosome to the mitochondrion has also been proposed. The “kiss and run” hypothesis suggests that the Tf-containing endosome directly contacts the mitochondrion,¹¹³ thereby bypassing the cytosol. The details of the mechanism remain to be determined.

P.623

The rate of iron entry into normoblasts is intimately related to heme biosynthesis.¹¹⁴ In less mature erythrocyte precursors, an optimal amount of heme may be necessary to sustain TfR1 synthesis.¹¹⁵ Furthermore, a decrease in intracellular free heme concentration induced by inhibitors of heme synthesis (e.g., isoniazid) leads to increased iron uptake, and an increase in intracellular free heme induced by inhibitors of globin synthesis (e.g., cycloheximide) has the opposite effect. These phenomena appear to reflect a feedback inhibition system that regulates the supply of iron according to the needs of the cell for hemoglobin synthesis. This is part of a highly coordinated erythroid regulatory system that acts to balance the amounts of α - and β -globin proteins and heme, avoiding toxic buildup of any intermediates of hemoglobin production.¹¹⁶

Iron Metabolism within Normoblasts

In the normal subject, ~80% to 90% of the iron that enters erythroid precursor cells is ultimately taken up by mitochondria and incorporated into heme. Most of the remainder is stored in ferritin.¹¹⁷ Granules of ferritin may sometimes be detected using the Prussian blue reaction.¹¹⁸ Normoblasts with Prussian blue-positive (siderotic) granules are called sideroblasts, and, if the granules persist after enucleation, the mature cells are called siderocytes. In normal individuals, approximately half of the normoblasts are sideroblasts, each containing less than five small granules. By electron microscopy, these normal siderotic granules are seen to be aggregations of ferritin, often surrounded by a membrane (siderosomes).¹¹⁹ Isolated molecules of ferritin not surrounded by a membrane may also be seen by electron microscopy but not with light microscopy. Another kind of sideroblast, the ringed sideroblast, is found only under pathologic circumstances (sideroblastic anemias; see Chapter 24). In the ringed sideroblast, siderotic granules form a full or partial ring around the nucleus, and electron microscopy reveals that the iron is deposited in mitochondria. The spleen plays an active role in the removal of the iron-laden mitochondria when cells enter the circulation.

It is intriguing that even though erythroid precursors require large amounts of iron and heme for hemoglobin synthesis, they have been found to express the heme exporter FLVCR and the iron exporter ferroportin. FLVCR, initially identified as the receptor for feline leukemia virus subgroup C which causes erythroid aplasia in cats, is highly expressed in early erythroid precursors. The loss of FLVCR in mice caused embryonic lethality due to the lack of definitive erythropoiesis.¹²⁰ When FLVCR was ablated postnatally, the mice developed a hyperchromic macrocytic anemia with proerythroblast maturation arrest. These studies suggest that FLVCR is necessary for survival of erythroid precursors. Because heme is toxic to cells at high concentrations, it is thought that FLVCR functions as a safety valve to prevent accumulation of excess heme early during erythroid differentiation.

Erythroid precursors also express ferroportin^{86,121} but its role in erythroid maturation is yet unclear. It is interesting that erythroid cells preferentially express non-IRE ferroportin transcript during the stages of rapid iron uptake, thus avoiding any iron-induced increase in ferroportin translation dependent on the IRE/IRP system.

Macrophage Iron Recycling

Although there are many types of tissue macrophages, those that participate in the catabolism of red blood cells can be subdivided into two categories. One type, exemplified by pulmonary alveolar macrophages, is able to phagocytose erythrocytes or other cells and convert the iron they contain into storage forms, but lacks the ability to return the iron to the circulation. This type of macrophage appears to retain the iron throughout its life span. The second type of macrophage, comprising the reticuloendothelial system, acquires iron in a similar fashion but is able to return it to the plasma. The latter macrophages, found especially in the sinuses of the spleen and the liver, play a primary role in the normal reutilization of iron from destroyed red cells, allowing completion of the iron cycle shown in Figure 23.4.

After erythrophagocytosis by reticuloendothelial macrophages, the red cell membrane is destroyed, heme is released from hemoglobin, and iron is liberated by heme oxygenase. The subcellular location of these events is not well defined. Subsequently, two phases of macrophage iron release are observed: an early phase, complete within a few hours after

erythrophagocytosis, and a later phase, taking place over a period of days.¹²² Iron is exported from macrophages through ferroportin, the iron exporter that is also found on the basolateral surface of absorptive enterocytes.²⁸ The early phase probably reflects immediate export of iron resulting from the sequential induction of ferroportin mRNA expression by heme released from hemoglobin, and ferroportin protein translation by heme-derived iron acting via the IRE/IRP system.¹²³ The later phase of iron release probably represents mobilization of stored iron in response to iron demand. This is likely achieved by modulating expression of hepcidin, the iron-regulatory hormone that causes degradation of macrophage ferroportin. Expression of hepcidin decreases when erythroid iron needs increase, allowing more ferroportin molecules to remain on the membrane of recycling macrophages.¹²⁴ Iron exported through ferroportin must be oxidized to be bound to transferrin. The ferroxidase reaction is catalyzed by the plasma copper protein, ceruloplasmin.¹²⁵ When the gene encoding ceruloplasmin was disrupted in mice, macrophages failed to release their iron at a normal rate, resulting in hypoferremia despite the presence of normal iron stores.¹²⁵ The abnormality was corrected by administering ceruloplasmin intravenously. A similar phenomenon was noted in aceruloplasminemic human subjects.¹²⁶ Ceruloplasmin probably acts by catalyzing the oxidation of ferrous iron to the ferric form, which is a prerequisite for iron binding by apotransferrin.

Because of the large daily iron flux through erythrophagocytosing macrophages (20 to 25 mg), iron release from macrophages is a critical determinant of the availability of iron for plasma transferrin and, consequently, for erythropoiesis. The anemia of inflammation, also called the anemia of chronic disease,¹²⁷ characterized by macrophage iron retention, illustrates the deleterious effects of perturbing the delicate balance between macrophage iron storage and release (see Chapter 45).

Intracellular iron in macrophages is stored in two compounds: ferritin and hemosiderin. Iron-free ferritin (apoferritin) exists as a sphere with a diameter of 13 nm.¹²⁸ It has a hollow central cavity, 6 nm in diameter, which communicates with the surface by six channels through which iron and other small molecules can enter and leave. The protein shell is constructed of 24 molecules of two distinct ferritin subunits, designated H (for heavy or heart) and L (for light or liver), and these proteins are ubiquitously expressed. H and L ferritins are highly homologous, suggesting that they were derived from a common ancestral protein. However, there are functional differences between the two subunits. Loss of ferritin H in mice causes early embryonic lethality indicating that there is no functional redundancy between the two ferritin subunits.¹²⁹ H chains contain a ferroxidase center not found in L chains and are able to oxidize iron.^{130,131} Ferritin shells rich in H chains reflect this property and acquire iron more rapidly,¹³² whereas those rich in L chains appear to be more stable and resistant to denaturation. The primary role of ferritin is cellular protection against oxidative damage that would be caused by highly reactive free iron.¹³³

At least 20 distinct ferritin heteropolymers, with varying proportions of L and H chains, have been isolated from human tissue.¹³⁴ Fully assembled, iron-free apoferritin has a molecular weight of approximately 400 to 500 kDa. When iron is

P.624

incorporated into the molecule, it is deposited in the central core. Theoretically, a single ferritin molecule could hold up to ~4,500 iron atoms. More often, molecules with 2,000 or fewer iron atoms are found. The iron is stored as a trivalent polymer of ferric hydroxide and phosphate.

Although H and L chains make up the abundant cytoplasmic ferritin molecules, a unique ferritin protein is present in mitochondria, and is encoded by a distinct intronless gene.¹³⁵ Mitochondrial ferritin appears to have a ferroxidase activity, making it most analogous to H-ferritin.¹³⁶ Although incompletely understood, the role of mitochondrial ferritin is important enough that it has been conserved among species and can even be found in fruit flies.¹³⁷

In a wide variety of cell types, the synthesis of apoferritin is stimulated by exposure to iron.¹³⁸ This effect of iron takes place at the translational level of protein synthesis, via the IRE/IRP system described earlier in the chapter. An iron-responsive element (IRE) found at the 5' end of ferritin mRNAs is both necessary and sufficient for the iron effect.¹³⁹ In red cell precursors, hemin rather than iron itself may exert a similar function.^{115,140}

Apoferritin is formed first, and iron is added later. A cytosolic iron chaperone, poly(rC)-binding protein 1 (PCBP1), delivers iron in the form of Fe²⁺ to ferritin.¹⁴¹ Iron then enters ferritin through one of the six penetrating channels. As it passes into the core, it is oxidized to the Fe³⁺ form by molecular oxygen, with apoferritin catalyzing the oxidative process.¹⁴² Iron is deposited irregularly and in varying amounts, forming microcrystals. Mobilization of iron from ferritin depends on iron reduction or chelation.

Ferritin is also found in plasma in small amounts (12 to 300 µg/L), and in the absence of inflammation,¹⁴³ the circulating ferritin concentration correlates roughly with the amount of iron in stores. Plasma ferritin appears to be actively secreted into plasma, primarily by macrophages^{144,145} and is iron-poor compared to tissue ferritin.

Hemosiderin was formerly distinguished from ferritin on the basis of solubility and the Perls Prussian blue reaction. However, these distinctions are not reliable; as with hemosiderin, ferritin can also be stained with Prussian blue and can exist in insoluble forms. Hemosiderin is not a precisely definable chemical entity.¹⁴⁶ It appears to be formed by incomplete degradation of ferritin and conglomeration of iron, ferritin proteins, and other subcellular constituents. It differs from ferritin in having a higher iron-to-protein ratio as well as being less soluble in aqueous solutions. Standard hemosiderin preparations may contain a variety of organic constituents, including proteins, lipids, sialic acid, and porphyrins. In most instances, hemosiderin appears to be derived from ferritin. Hemosiderin appears to represent a more stable and less available form of storage iron than ferritin. Newly deposited or newly mobilized iron enters or leaves the ferritin compartment. Only after prolonged storage or continued mobilization does the hemosiderin compartment change in size.

Iron Metabolism in Other Tissues

Iron is required in small amounts by all tissues for the synthesis of iron-containing enzymes and proteins, including cytochromes, catalase, ribonucleotide reductase, ferrochelatase, and globins. Cells are generally thought to acquire their iron from transferrin through binding to cell-surface transferrin receptor 1, although there is little experimental evidence that this is the major iron acquisition mechanism in most cases. Aside from erythroid precursors and tumor cells, iron uptake by hepatic parenchymal cells has been most extensively studied. Normally, approximately 5% of iron leaving plasma is accounted for by this pathway.¹⁴⁷ This fraction increases markedly when transferrin saturation increases or when erythropoiesis is depressed. Transferrin is not essential for iron assimilation by hepatocytes or most other nonhematopoietic cells, as demonstrated by atransferrinemic human patients and hypotransferrinemic (hpx) mice, both of which develop marked iron overload in nonhematopoietic tissues.

The placenta also accepts iron from transferrin and may do so even at relatively low plasma iron levels, thus effectively competing with the maternal erythroid bone marrow. The export of iron from placental trophoblast into fetal circulation occurs through ferroportin, and this step is controlled by fetal hepcidin.¹²⁴ Some iron in placenta is stored within ferritin and hemosiderin.

Skeletal muscle uses iron for myoglobin synthesis and also maintains an iron storage pool that, although large, is not easily mobilized for use by other tissues.¹⁴⁸ Proliferating cells in many tissues have increased numbers of transferrin receptors compared to their quiescent counterparts, reflecting their need for iron.

IRON DEFICIENCY ANEMIA

Pathogenesis of Iron Deficiency Anemia

Although its handling is frequently termed "iron metabolism", iron itself is not metabolized; iron disorders are of iron balance or distribution. Iron deficiency anemia, hemochromatosis, and the anemia of chronic disease/inflammation are each examples of this principle.

Three pathogenic factors are implicated in the anemia of iron deficiency. First, hemoglobin synthesis is impaired as a consequence of reduced iron supply. Second, there is a generalized defect in cellular proliferation. Third, survival of erythroid precursors and erythrocytes is reduced, particularly when the anemia is severe.

When transferrin saturation falls below ~15%, the supply of iron to the marrow is inadequate to meet basal requirements for hemoglobin production (generally ~25 mg of iron daily in average adults). As a result, the amount of free erythrocyte protoporphyrin increases, reflecting the excess of protoporphyrin over iron in heme synthesis. Globin protein synthesis is reduced and each cell that is produced contains less hemoglobin, resulting in microcytosis and hypochromia. This is the normal adaptive response to iron deficiency in humans and mice. If globin synthesis was not decreased in heme deficiency, misfolding and precipitation of excess globin chains would lead to apoptosis. Globin synthesis is controlled by heme availability at both the transcriptional and translational levels. Heme regulates globin gene expression by its ability to bind a transcription suppressor Bach1. When heme is deficient, Bach1 associates with small Maf proteins (sMafs) and causes transcriptional repression of globin genes.^{149,150} When heme is abundant, heme binding to Bach1 causes its dissociation from sMafs and Bach1 degradation,^{151,152} permitting sMaf interaction with transcriptional activators to increase expression of globin genes.

On the translational level, heme regulates globin synthesis by binding to and controlling the activity of heme-regulated eIF2α kinase (HRI).¹⁵³ HRI functions by phosphorylating the α subunit of a key regulatory translation initiation factor eIF2 and preventing its participation in the initiation of translation. With high intracellular heme concentrations, heme binds to

HRI and renders it inactive, but in heme deficiency, heme dissociates from HRI, and the kinase is activated by autophosphorylation. HRI then phosphorylates eIF2 α , preventing the recycling of eIF2 for another round of protein synthesis initiation, resulting in reduced globin protein synthesis and preventing formation of toxic globin precipitates in the absence of heme. In Hri^{-/-} mice, the adaptive hypochromic and microcytic response to iron deficiency was absent.¹¹⁶ Iron deficiency and consequently decreased heme levels instead resulted in aggregation of globins within the erythrocytes and their precursors, causing increased apoptosis of

P.625

erythroid precursors in the bone marrow and spleen, and accelerated destruction of mature RBCs that were hyperchromic and normocytic.

Cellular proliferation is also restricted in iron deficiency, and red blood cell numbers fall. Although there is relative erythroid hyperplasia in the bone marrow, both the degree of erythroid hyperplasia and the reticulocyte count are low for the degree of anemia. There is a significant component of "ineffective erythropoiesis" in iron deficiency, and a proportion of immature erythroid cells in iron-deficient subjects are so defective that they are rapidly destroyed. Their iron is reused within the bone marrow, making the interpretation of ferrokinetic studies more complicated.^{154,155}

In iron deficiency, survival of circulating erythrocytes is normal or somewhat shortened.^{156,157,158,159} Cross-transfusion studies indicate that the shortened survival results from an intracorporeal defect. There is a strong correlation between the degree to which red cell survival is shortened and the proportion of morphologically abnormal cells on blood smear.¹⁵⁶ The principal site of destruction is the spleen.¹⁵⁸ The reduced erythrocyte viability is associated with decreased membrane deformability.¹⁶⁰ This abnormality appears to result from oxidative damage to the membrane.^{160,161}

Other iron-containing proteins are also reduced in iron deficiency, and some of these may be responsible for clinical and pathologic manifestations. It is suggested that many of the enzymes are depleted in proportion to the degree of anemia.¹⁶² Among the iron proteins reduced in iron deficiency are cytochrome c,^{162,163} cytochrome oxidase,^{164,165} α -glycerophosphate oxidase,^{166,167} muscle myoglobin,^{162,163} succinic dehydrogenase, and aconitase.

In iron-deficient rats, impaired exercise performance correlated with reduced levels of α -glycerophosphate oxidase in muscle.^{166,167} As a result, glycolysis was impaired, which led to lactic acidosis and, in turn, adversely affected work performance. Lactic acidosis was also noted in a patient with severe iron deficiency anemia.¹⁶⁸ Levels of catecholamines are increased in the blood and urine of iron-deficient patients and animals.^{169,170} The increase is explained in part by decreased tissue levels of monoamine oxidase.^{171,172} Conceivably, a disturbance in catecholamine metabolism may contribute to the behavioral disturbances seen in iron-deficient children.^{173,174} As described later, there are several characteristic epithelial changes in iron deficiency. The pathogenesis of these abnormalities is not understood, but it is reasonable to assume that deficiencies in tissue iron enzymes are at fault.

TABLE 23.2 GENES INVOLVED IN HEREDITARY IRON DEFICIENCY ANEMIA

Protein (Gene Symbol)	Chromosome	Protein Function	Disease Caused by Mutations
DMT1 (SLC11A2)	12	Transmembrane iron transporter	Hypochromic, microcytic anemia, usually with hepatic iron overload ^{109,110,111}
Glutaredoxin 5 (GLRX5)	14	Participates in iron-sulfur cluster biogenesis	Anemia with iron overload and sideroblasts ¹⁷⁵
Transferrin (TF)	3	Plasma iron-binding protein; ligand for TfR1 and TfR2	Atransferrinemia, iron deficiency anemia with tissue iron overload ^{94,95,97}
Ceruloplasmin (CP)	3	Plasma ferroxidase	Aceruloplasminemia, mild iron deficiency anemia associated with iron accumulation in the liver and brain ¹⁷⁶
Matriptase-2 (TMPRSS6)	22	Hepcidin suppressor, acts by cleaving membrane hemojuvelin	Iron-refractory iron deficiency anemia (IRIDA) ^{177,178,189,190}

Modified from Andrews NC. Forging a field: the golden age of iron biology. *Blood* 2008;112:219-230.

Genetic Forms of Iron Deficiency Anemia

Genes involved in hereditary iron deficiency anemia are listed in Table 23.2.^{81,97,175,176,177,178} The main biologic and clinical difference in genetic forms of iron deficiency anemia are outlined in Table 23.3.

Several forms of genetic iron deficiency anemia are associated with hypochromic microcytic anemia and iron overload outside of the erythron. These are caused by autosomal recessive mutations in several genes and are exceedingly rare. DMT1 (SLC11A2) encodes an iron transporter involved in dietary iron absorption and iron transfer from Tf/TfR endosomes into the cytosol of erythroid precursors. Glutaredoxin 5 (GLRX5) is an enzyme involved in mitochondrial iron-sulfur cluster biogenesis. The human patients carrying these mutations have similar blood films and erythrocyte abnormalities, but also have hepatic iron overload that is not fully explained by their transfusion histories.^{109,110,111,175,179,180} Deficiency of serum transferrin, called hypotransferrinemia or atransferrinemia, is due to mutations in the transferrin gene itself.^{97,181} This interrupts iron delivery to erythroid precursors, triggering an increase in intestinal iron absorption and consequent tissue iron deposition. Deficiency of another major plasma protein, ceruloplasmin, also causes mild iron deficiency anemia associated with iron accumulation in the liver and brain.¹⁷⁶ Iron deficiency results from lack of ferroxidase activity needed to mobilize iron from storage.^{176,182,183}

Some patients have congenital, iron-refractory iron deficiency anemia (IRIDA) without iron overload.^{178,184,185,186,187,188,189} and¹⁹⁰ The disease is caused by recessive mutations in the *Tmprss6* gene, which encodes serine protease matriptase-2. This gene is mutated in a novel mouse mutant, Mask.¹⁹¹ In addition to a hair pattern that led to the strain name, Mask mice have severe iron deficiency anemia attributable to elevated hepcidin expression. Matriptase-2 is highly expressed in the liver, and acts by cleaving hemojuvelin, a BMP pathway coreceptor and a key regulator of hepcidin expression.^{56,178} Measurement of serum hepcidin concentrations in IRIDA patients confirmed that hepcidin levels were much higher than would be expected for the degree of iron deficiency and anemia, where hepcidin is usually undetectable.^{178,189,190} How *TMPRSS6* expression or activity is regulated is still unknown. Further studies will be needed to evaluate the possibility that less severe or heterozygous mutations increase susceptibility to common, acquired iron deficiency anemia. In genome-wide association studies (GWAS), common variants of *TMPRSS6* were associated with alterations in hemoglobin levels, serum iron,

P.626

or erythrocyte volume,^{192,193,194} and¹⁹⁵ suggesting that *TMPRSS6* has a critical role in maintenance of iron homeostasis and normal erythropoiesis.

TABLE 23.3 MAIN BIOLOGIC AND CLINICAL DIFFERENCES IN GENETIC FORMS OF IRON DEFICIENCY ANEMIA

	DMT1	Glutaredoxin 5	Atransferrinemia	Aceruloplasminemia	TMPRSS6 (Matriptase-2)
Age at diagnosis	At birth	Usually midlife	Late onset provided some Tf is present	Late onset with moderate anemia	18-24 mo
Liver iron overload	Yes	Yes	Yes	Yes	No
Brain damage	No	No	No	Yes	No
Serum iron	High	High	Low	Low	Low
Transferrin saturation	High	High	High or nonmeasurable	Low	Low
Ringed sideroblasts	No	Yes	No	No	No
Hepcidin levels	Low to normal	Not yet measured	Low	Low	High for anemia

Ferritin	Low to mildly elevated	High	High	High	Low to normal

CLINICAL FEATURES OF IRON DEFICIENCY

Stages in the Development of Iron Deficiency

When it is not a result of major blood loss, iron deficiency is the end result of a long period of negative iron balance. As the total body iron level begins to fall, a characteristic sequence of events ensues. First, the iron stores in the hepatocytes and the macrophages of the liver, spleen, and bone marrow are depleted. Once stores are gone, plasma iron content decreases, and the supply of iron to marrow becomes inadequate for normal hemoglobin production. Consequently, the amount of free erythrocyte protoporphyrin increases, production of microcytic erythrocytes begins, and the blood hemoglobin level decreases, eventually reaching abnormal levels.

This progression corresponds to three recognized stages. The first stage, also called prelatent iron deficiency or iron depletion, represents a reduction in iron stores without reduced serum iron levels.¹⁹⁶ This stage is usually detected by a low serum ferritin measurement, unless inflammation is present in which case serum ferritin does not reflect storage iron.¹⁴³ Latent iron deficiency is said to exist when iron stores are exhausted but the blood hemoglobin level remains higher than the lower limit of normal.¹⁹⁷ In this second stage, certain biochemical abnormalities of iron-limited erythropoiesis may be detected, including reduced transferrin saturation, increased TIBC,¹⁹⁸ increased free erythrocyte protoporphyrin,¹⁹⁹ increased zinc protoporphyrin,²⁰⁰ and increased serum transferrin receptor (sTfR).²⁰¹ The mean corpuscular volume usually remains within normal limits, but a few microcytes may be detected on a blood smear. Patients report generalized fatigue or malaise, even though they are not yet anemic.

Finally, in the third stage, the blood hemoglobin concentration falls below the lower limit of normal, and iron deficiency anemia is apparent. Iron-containing enzymes, such as the cytochromes, also reach abnormally low levels during this period. Clinical manifestations include a constellation of constitutional symptoms: fatigue, decreased exercise tolerance with tachycardia, dermatologic manifestations, decreased intellectual performance, dysphagia, depression, and restless legs syndrome.²⁰² This progression forms the basis for the stages of iron deficiency outlined in Table 23.4. It has been confirmed by experiments in which normal volunteers were gradually depleted of iron by phlebotomy.^{203,204}

TABLE 23.4 STAGES IN THE DEVELOPMENT OF IRON DEFICIENCY

	Stage 1 (Prelatent)	Stage 2 (Latent)	Stage 3 (Anemia)
Bone marrow iron	Reduced	Absent	Absent
Serum ferritin	Reduced	<30 µg/L	<30 µg/L
Transferrin saturation	Normal	<16%	<16%
Free erythrocyte protoporphyrin, zinc protoporphyrin	Normal	↑	↑
Serum transferrin receptor	Normal	↑	↑
Reticulocyte hemoglobin content	Normal	↓	↓
Hemoglobin	Normal	Normal	Reduced
Mean corpuscular volume	Normal	Normal	Reduced
Symptoms	Rare	Fatigue, malaise in some patients	Pallor, pica, epithelial changes

↑, increased; ↓, decreased.

Prevalence

Iron deficiency is the most common nutritional deficiency in both developing and developed countries. Iron deficiency anemia may be defined by cutoff hemoglobin values of 12.1 g/dl in women and 13.8 g/dl in men at or near sea level, with

higher cutoff values at high altitude.²⁰⁵ In the United States, the most comprehensive surveys for iron deficiency anemia have been the National Health and Nutrition Examination Surveys (NHANES). According to data from NHANES III, covering the years 1988 to 1994, the

P.627

prevalence of hypoferrremia in the United States was <1% in adult men <50 years of age, 2% to 4% in adult men >50 years of age, 9% to 11% in menstruating teenagers and women, and 5% to 7% in postmenopausal women. Inasmuch as serum ferritin is an acute phase reactant regulated by inflammation, these data may underestimate the prevalence of anemia in some populations, particularly the elderly. Recent analyses have estimated prevalence of iron deficiency anemia in the elderly (>65 years of age) and extreme elderly (>75 years of age) ranging from 10% to up to 36%.^{206,207,208}

Iron deficiency is particularly common in young children and pregnant women. Iron deficiency was detected in 9% of infants and toddlers, with anemia in approximately one third of those children.²⁰⁹ In infancy, the occurrence of iron deficiency was equal in both sexes. It is usually detected between the ages of 6 and 20 months. The peak incidence was at a younger age in infants born prematurely than in those born at term, because premature infants do not have full opportunity to acquire maternal iron during the third trimester. The prevalence of iron deficiency was also higher among people living in chronic poverty.²¹⁰ Iron deficiency tends to run in families, possibly as a result of economic factors. If an iron-deficient child is identified, the mother and siblings of that child are frequently also deficient. Despite the prevalence of iron deficiency anemia in these populations, the US preventative services task force recommends screening only for pregnant women.²¹¹

Etiology

Iron deficiency occurs as a late manifestation of prolonged negative iron balance, as a result of major blood loss, or because of failure to meet an increased physiologic need for iron. The normal mechanisms for maintaining iron balance were discussed earlier in this chapter. Factors leading to negative iron balance, increased requirements, or inadequate iron for erythropoiesis are listed in Table 23.5. In many instances, multiple etiologic factors are involved. The association of a marginal diet with some source of blood loss, such as that associated with menstruation, is a common combination. Another example is hookworm infestation, which produces anemia primarily in those people whose diets are marginally adequate.

Diet

The total amount of iron in the diet roughly correlates with caloric content; in the United States, the average diet contains ~6 mg of iron per 1,000 kcal. The bioavailability of dietary iron in specific foods was described earlier in this chapter.

The early stages of human evolution were characterized by hunter-gatherer food patterns and by diets rich in meat. In evolutionary terms, agriculture is a recent development to which humans have not fully adapted. Thus, individuals whose diets are rich in meat, a source of heme iron, usually absorb more iron from their diets than those who subsist on grains and vegetables. The increased prevalence of iron deficiency among the economically deprived and people in developing countries is explained in part by the fact that heme iron is less abundant in their diets.

Because many factors influence the bioavailability of iron, it is difficult to make recommendations about the optimal amount of iron in the diet. In the usual mixed diets of Western countries, adult men should consume 5 to 10 mg/day, and adult women should consume 7 to 20 mg/day.¹⁹⁶ Because women are usually smaller and consume less food than men, and because their requirements are greater, their daily iron intake may be marginal. Iron deficiency is rarely seen in American men as a result of diet alone. Exceptions to this rule are sufficiently unusual to justify case reports.²¹²

In many countries, foods are fortified to compensate for the insufficient amounts of iron in the diet.^{213,214} Selection of the food to fortify and the iron compound to use in fortification requires consideration of a number of factors. The iron salt should be absorbable but should not affect appearance, taste, or shelf life. The salt must be chosen with consideration of the food to be fortified, and that choice must be individualized to the target population. In Western countries, wheat flour is a typical choice; its use is widespread, and highly available ferrous salts can be used in such products as bread because their shelf life is inherently short. Target foods in other countries include salt, sugar, rice, and condiments. For infants, fortified milk- or soy-based formulas and dry cereals are important sources of iron in the diet.

TABLE 23.5 ETIOLOGIC FACTORS IN IRON DEFICIENCY ANEMIA

NEGATIVE IRON BALANCE

Decreased Iron Intake

Inadequate diet
Impaired absorption
Achlorhydria
Gastric surgery
Celiac disease
H. pylori infection
Duodenal bypass
Drugs that increase gastric pH
Tannins, phytates, bran
Competing metals
Inflammation, ↑ Hepsidin

Increased Iron Loss

Blood donation
Iatrogenic: diagnostic phlebotomy for testing
Gastrointestinal bleeding
Intestinal parasites
Anatomic lesions: hemorrhoids, gastritis, diverticulosis, varices, hiatal hernia, Meckel's diverticulum, arteriovenous malformation, peptic ulcer
Neoplasm
Inflammatory bowel disease
Milk-induced enteropathy (infants)
Use of salicylate or nonsteroidal anti-inflammatory agents (NSAIDS)
Excessive menstrual flow
Gynecologic neoplasm
Bladder neoplasm
Epistaxis
Hemoglobinuria
Self-induced bleeding (autophlebotomy)
Pulmonary hemosiderosis
Tuberculosis
Bronchiectasis
Hereditary hemorrhagic telangiectasia
Anticoagulant, antiplatelet therapies
Chronic hemodialysis
Runner's anemia

Increased Requirements

Infancy

Pregnancy

Lactation

Genetic Forms of Iron Deficiency Anemia

P.628

Impaired Absorption

Achlorhydria is common in iron-deficient subjects, both as a result of the deficiency and as a factor in its development.²¹⁵ Gastric acid facilitates absorption of nonheme iron,²¹⁶ probably by increasing its solubility rather than affecting the activity of the proton-symporter DMT1, and absorption of inorganic iron is profoundly impaired in patients with atrophic gastritis. Therapeutic measures used to reduce gastric acidity, such as the administration of antacids and drugs that block acid production, also impair iron absorption but usually not to a clinically significant degree. Gastric infection with *Helicobacter pylori* is now recognized as an important cause of otherwise unexplained iron deficiency anemia, which responds to eradication of the bacterial infection.²¹⁷

Iron deficiency anemia is a common complication of gastric surgeries, including total gastrectomy,²¹⁸ partial gastrectomy,²¹⁹ and vagotomy with gastroenterostomy.²²⁰ Reduction in gastric acidity is only one factor in the impaired iron absorption that follows such operations. Other gastric secretions that aid in iron absorption may also be lost.²²¹ Also, because most iron absorption takes place in the duodenum, the rapid intestinal transit that follows loss of the reservoir function of the stomach may lead to decreased absorption. For the same reason, iron deficiency is more common when the duodenum is surgically bypassed.²²⁰ Finally, recurrent bleeding, as well as increased sloughing of iron-containing epithelial cells, may contribute to the development of postgastrectomy anemia.²²¹

In addition to gastrectomy, other defects in the gastrointestinal tract may lead to malabsorption of iron, contributing to the development of iron deficiency. The anemia associated with celiac disease (gluten sensitivity, sprue, idiopathic steatorrhea) is often hypochromic rather than megaloblastic^{222,223}; in fact, iron deficiency anemia may be the initial and dominant manifestation of celiac disease, with steatorrhea detectable only by laboratory test analysis.^{222,224} Both malabsorption and intestinal blood loss are factors in the development of iron deficiency.²²³ Most patients with tropical sprue are deficient in iron.²²⁵

Copper Deficiency

It has long been known that copper deficiency is associated with abnormalities in iron metabolism and iron deficiency anemia. In recent years, it has become clear that this is due, at least in part, to the importance of the copper-containing ferroxidases ceruloplasmin and hephaestin. As mentioned earlier in this chapter, these enzymes are required for the optimal mobilization of iron from cells to plasma. They oxidize Fe^{2+} exported by ferroportin into Fe^{3+} form which can then bind to apotransferrin.

Blood Loss

Blood loss is a significant cause of iron deficiency anemia. It is important not only because of its prevalence, but also because the accurate detection, precise diagnosis, and proper management of the bleeding lesion may be of far greater importance to the ultimate well-being of the patient than repletion of iron stores. Each 1 ml of red blood cells contains ~1 mg of iron. Thus, assuming the consumption of an average diet, chronic RBC loss of as little as 1 to 2 ml/day can result in a negative iron balance.

Gastrointestinal Bleeding

Gastrointestinal bleeding is the most common cause of iron deficiency in adult men and is second only to menstrual blood loss as a cause in women. Any hemorrhagic lesion of the alimentary tract may cause iron deficiency. Most commonly, the lesions cause occult bleeding or the steady loss of small amounts of blood. They may go unnoticed or may be tolerated until the symptoms of anemia supervene. The list of etiologies presented here is not meant to be comprehensive; many other, less common, lesions have been reported to occur in association with isolated cases of iron deficiency anemia.

Two thirds of patients with hemorrhoids experience rectal bleeding, which is usually obvious to the patient. Nevertheless, a large majority of patients allow at least 1 year to elapse before seeking medical attention, and perhaps one third wait for more than 10 years. Nevertheless, although hemorrhoids are frequently associated with iron deficiency anemia, the clinician should be reluctant to accept them as the only bleeding lesions; a careful investigation is warranted because hemorrhoids may divert attention from another, less obvious, lesion elsewhere in the alimentary tract.

Upper gastrointestinal bleeding is typically due to duodenal or gastric ulcers or gastritis, all of which can cause sufficient blood loss to result in iron deficiency. Certain drugs are associated with gastrointestinal bleeding. Of these, nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, are the most important. NSAID administration causes mucosal damage manifested by petechial hemorrhage, erosions, and ulcers. The problem is more likely to occur in elderly patients and women and with higher ("anti-inflammatory") doses than with lower ("analgesic") ones.²²⁶

Studies with aspirin demonstrate that at doses of 2 to 6 g daily, 70% of patients have gastrointestinal bleeding at an average rate of 5 ml/day.²²⁷ Regular use of aspirin more often than four times weekly is associated with bleeding.²²⁸ The incidence of aspirin-induced bleeding has probably decreased as the pattern of analgesic use has changed.

Acetaminophen, which is not associated with gastrointestinal bleeding, has become more popular than aspirin as an over-the-counter analgesic. Newer NSAID preparations are also less likely to cause significant gastrointestinal blood loss. The popularity of aspirin is on the rise again for prophylaxis of coronary artery disease, but in low doses. Other drugs associated with gastrointestinal bleeding include stanozolol, anticoagulants, antiplatelet agent therapy for coronary artery disease corticosteroids, and ethacrynic acid.

Iron deficiency anemia occurs in ~15% of patients with esophageal hiatal hernia.²²⁹ Anemia is particularly common (30%) with the paraesophageal variety of lesions and in large hernias.²³⁰ Reasons for the bleeding include reflux esophagitis and trauma to the gastric mucosa at the neck of the hernial sac.²²⁹ Anemia may be the presenting manifestation even in the absence of dyspeptic symptoms.

Colonic diverticuli can also bleed in patients with diverticulosis and diverticulitis. Usually, the blood loss is small and intermittent and may resemble the pattern of hemorrhoidal bleeding. Intestinal bleeding can also result from the presence of adenomatous polyps. A careful investigation for other sources of intestinal blood loss is warranted to exclude the possibility of a neoplasm.

Iron deficiency anemia may be the first sign of a malignant neoplasm of the gastrointestinal tract, and management of the bleeding lesion is important.^{143,231,232,233} Carcinoma of the cecum is often clinically silent until anemia occurs. Less often, in carcinomas of other parts of the colon, as well as of the stomach and the ampulla of Vater, iron deficiency anemia may be the only initial symptom.

In a survey of 32 patients with ulcerative colitis, 26 (81%) had iron deficiency anemia.²³⁴ Average fecal blood loss of 6 to 25 ml/day was noted in five patients who were moderately anemic with relatively mild symptoms of colitis.

An important cause of gastrointestinal blood loss in tropical areas is infection with intestinal and genitourinary parasites,²³⁵ including whipworm, *Trichuris trichiura*²³⁶; hookworm, *Necator americanus* or *Ancylostoma duodenale*^{237,238}; and schistosomes.²³⁹ Hookworm is particularly important, affecting some 20% of the world's population.²²⁵ It is endemic in a zone extending from the southern United States to northern Argentina in

P.629

the Western hemisphere, as well as in Mediterranean countries, South Asia, and Africa. The worms attach to the upper small intestine and suck blood from the host. The amount of blood lost is proportional to the number of worms harbored, which can be estimated by the fecal excretion of hookworm eggs. Female subjects harboring >100 worms (5 ml/day of blood loss) and male subjects harboring >250 worms (12.5 ml/day of blood loss) tend to become anemic.²³⁷ Other factors affecting iron balance including an iron-deficient diet, repeated pregnancies, and achlorhydria are contributory factors in development of hookworm anemia. At one time, many people believed that hookworm anemia resulted from elaboration of a toxin, but this is not the case. The anemia has all of the characteristics of iron deficiency and may be improved with iron therapy, whether or not the worms are removed. Conversely, removal of worms with an effective antihelminthic agent does not correct the anemia unless iron stores are replenished.

Schistosomiasis and trichuriasis are other parasitic infections associated with iron deficiency.²³⁵ With *Schistosoma mansoni*, blood loss is from the intestine, whereas with *Schistosoma haematobium* the loss is from the urinary tract.²³⁹ *Trichuris* (whipworm) has caused iron deficiency in inhabitants of Central America.²³⁶

Menstruation

Menstrual blood loss is the most common cause of iron deficiency in women.^{8,240,241,242} In healthy normal women, menstrual blood flow averages ~35 ml per menstrual period, and the upper limit of normal is ~80 ml per period. Although flow varies considerably among different women, it is remarkably constant from one period to the next in the same person. In Swedish women with a dietary intake of ~10 mg of iron per day, 67% of women with menstrual blood loss >80 ml per period were anemic.^{240,241} In another study, British women with iron deficiency anemia lost an average of 85 ml per period.²⁴² In contrast, a Canadian population with flows >80 ml per period had no overt anemia or hypoferrremia.²⁴³

Menstrual blood flow is increased by the use of certain intrauterine contraceptive devices²⁴⁴ and is reduced by the use of oral contraceptives. Estimating menstrual blood loss from information obtained in interviews is difficult because few women have a basis for determining the normality of their flow. It is important to elicit a history including a detailed description of the events during each menstrual period. Any of the following findings are indications of excessive menstrual flow: (a) inability to control flow with tampons alone; (b) use of more than 12 pads per period or 4 per day, unless the patient is unusually fastidious; (c) passage of clots, especially if they are larger than ~2 cm in diameter or if they persist after the first day; and (d) period duration exceeding 7 days.

Blood Donation

There are 5 million regular blood donors in the United States,²⁴⁵ and regular blood donation is an important source of iron loss. Each unit of blood donated contains 200 ml RBC²⁴⁶ equaling ~200 mg of iron. In most blood centers, a hemoglobin concentration, which is an insensitive determination for iron status, is the only indicator for iron deficiency anemia. As assessed by serum ferritin concentration, iron stores were reduced in 8% of male and 23% of female blood donors.²⁴⁵ The authors concluded that the use of iron supplements decreased the incidence of deficiency, and should be recommended to people who choose to donate more than once or twice a year. In a recent analysis of the RISE (Retrovirus Epidemiology Donor Iron Status Evaluation) study,²⁴⁷ for frequent blood donors, two thirds of women and almost half the men were iron deficient: the true prevalence among regular donors is even higher, inasmuch as the RISE study enrolled only frequent donors who had been accepted for donation, and excluded those deferred because of anemia. The unavoidable conclusion is that presently, blood collection practices fail to protect committed blood donors from iron deficiency.²⁴⁸ Re-examination of measures to prevent iron deficiency in women of child-bearing age by iron replacement after donation²⁴⁹ may now be in order to protect donors better, including changes in evaluation of iron status, in the hemoglobin standard, and internally between donations.²⁵⁰

Alveolar Hemorrhage

Acute hemorrhage into the pulmonary alveoli may be severe enough to cause the blood hemoglobin level to fall 1.5 to 3.0 g/dl in 24 hours.²⁵¹ Reticulocytosis and hyperbilirubinemia often accompany such episodes, leading to an incorrect diagnosis of hemolytic anemia. Iron in the shed blood is converted to hemosiderin by pulmonary macrophages, but it cannot be used for hemoglobin synthesis. Thus, repeated hemorrhages can lead to iron deficiency despite a normal total amount of body iron. Hemoptysis and alveolar infiltrates are the other prominent manifestations. However, if the hemorrhages are small, the hemoptysis may be unnoticed, making the diagnosis difficult without a chest x-ray examination. Patients may swallow the blood-containing sputum, rendering the stools positive for occult blood and resulting in further diagnostic confusion.

Idiopathic pulmonary hemosiderosis, an illness of children and young adults, is characterized by alveolar hemorrhage that is not due to another form of lung disease.^{252,253} Iron deficiency anemia almost invariably accompanies the disease and may be the initial and only symptom. Hemoptysis and alveolar infiltrates, however, are common manifestations. Interstitial fibrosis may develop after repeated episodes, with dyspnea, clubbing, and even cor pulmonale.

Anemia is also a common finding in antiglomerular basement membrane antibody disease (Goodpasture syndrome).^{253,254} The presence of renal disease distinguishes this illness from other forms of pulmonary hemosiderosis, but kidney involvement may not be evident early in the course of the disease or the degree of proteinuria or microscopic hematuria may be modest. Eventually, however, most patients develop azotemia. Focal or diffuse glomerulonephritis is evident from renal biopsy, and linear deposits of immunoglobulins are characteristic of, although not completely specific for, the disease. Detection of antibasement membrane antibodies in serum is ~80% to 85% sensitive and 98% specific for the diagnosis.²⁵¹

Other illnesses associated with pulmonary alveolar hemorrhage include rapidly progressive glomerulonephritis, systemic lupus erythematosus, and certain other collagen vascular diseases and systemic vasculitides. The presence of antineutrophil cytoplasm antibodies or other autoantibodies is considered a particularly poor prognostic sign in patients with pulmonary hemosiderosis.²⁵² Alveolar hemorrhage is also observed as a toxic reaction to trimellitic anhydride, d-penicillamine, or lymphangiography.

Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria can result in urinary iron losses averaging 1.8 to 7.8 mg/day.²⁵⁵ Consequently, this rare disorder often is complicated by hypoferremia and hypochromic anemia.²⁵⁶ Hemoglobinuria in other disorders, such as the erythrocyte fragmentation syndromes associated with prosthetic cardiac valves, also may be complicated by iron deficiency.^{257,258}

Factitious Anemia

Self-induced blood-letting (autophlebotomy) is an unusual cause of iron deficiency.^{259,260} In almost all reported instances, such anemia occurred in unmarried women in paramedical occupations. Blood was removed by venipuncture or injuring preexisting

P.630

hemorrhoids, by laceration of the gastrointestinal tract with such instruments as knitting needles, or by means that remained obscure. A single case was reported in which an infant apparently developed severe iron deficiency as a result of deliberate parental action in which all iron from the child's diet was removed.²⁶¹

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia is an uncommon disorder characterized by recurrent hemorrhages from the nose, gastrointestinal tract, and other sites. Iron deficiency anemia, sometimes very difficult to control, is an important complication of the illness.²⁶²

Iatrogenic Blood Loss

Diagnostic phlebotomy can result in substantial iron losses in patients with chronic disorders, particularly in hospitalized patients.^{263,264} In a study of 100 adult hospital inpatients in the 1980s, the average blood loss from diagnostic phlebotomy was 12.4 ml/day or 175.0 ml over the course of hospitalization on general wards.²⁶³ Patients in intensive care units lost an average of 41.5 ml/day or 762.0 ml during their stay. Of the 100 patients, 36 required blood transfusions, in part because of the losses from phlebotomy. Phlebotomy can contribute to a negative iron balance, and in patients with marginal iron stores, may precipitate or aggravate iron deficiency anemia and prevent compensatory erythropoiesis.

Chronic Renal Failure Treated with Hemodialysis

Iron deficiency affects a significant fraction of patients treated with hemodialysis now that the anemia related to chronic kidney disease is treated with pharmacologic agents and blood transfusions are restricted.^{265,266} Absolute iron deficiency results from the loss of blood associated with the dialysis process and diagnostic tests. Gastrointestinal blood losses may also be substantial, averaging 6.27 ml/day in one study.²⁶⁷ Telangiectasias are among the most common bleeding gastrointestinal lesions in patients with renal failure. Other factors contributing to negative iron balance include reduced dietary iron intake and malabsorption of iron caused by the aluminum hydroxide used to control hypophosphatemia.

Administration of erythropoiesis stimulating agents (ESA) results in a "functional iron deficiency" even when body iron stores are replete.²⁶⁸ The intense, periodic erythropoietic stimulus due to ESA therapy exceeds the mobilization of iron from macrophages, so that adequate transferrin-bound iron is not available to red blood cell precursors.^{268,269} and ²⁷⁰ For this reason, parenteral iron supplementation is often provided as an adjunct to ESA therapy in patients with ESKD.^{143,268}

Runner's Anemia

Iron deficiency anemia can occur in long-distance runners.²⁷¹ Over 50% of regular joggers and competitive runners become iron deficient.²⁷² Mild mechanical hemolysis accompanies strenuous exercise, resulting in hemoglobinemia and hemoglobinuria (also called march hemoglobinuria). Gastrointestinal bleeding contributes to blood loss and iron deficiency.^{272,273} and ²⁷⁴ Fecal blood excretion increases substantially after a race or an intense training exercise and may reach 5 to 7 ml/day. Stress, intestinal ischemia, and the jarring effect of running have been advanced as possible explanations for the gastrointestinal blood loss.

Decreased Total Body Iron at Birth

Body iron concentration in normal neonates averages ~75 to 100 mg/kg weight. Similar concentrations are found throughout fetal development, resulting in a linear relationship between body iron and body weight. Newborn babies in the upper range of normal birth weights have more iron than those in the lower range. Premature infants are at higher risk of iron deficiency during the first year of life, because they have not had the full opportunity to accumulate iron stores during the third trimester of gestation.

Newborn iron levels can be influenced by the technique that the obstetrician uses to clamp the umbilical cord at delivery.²⁷⁵ As much as 100 ml of fetal blood may remain in the placenta with early clamping of the cord. Cord clamping delayed for only 3 minutes can result in a 58% increase in red cell volume. If delayed clamping is impractical, as in cesarean section procedures, a similar effect can be achieved by clamping the cord at the placental end, raising the clamp, and allowing gravity to drain the cord.²⁷⁶ Although the newborn has no immediate need for these erythrocytes, the iron they contain can be used later to meet the demands of growth.

The fetus is an effective scavenger of maternal iron, in which fetal hepcidin controls the placental transfer of iron from maternal plasma to the fetal circulation,¹²⁴ therefore, maternal iron stores have little or no effect on the body iron stores of the newborn.²⁷⁷ No difference was found between the hemoglobin values in infants of anemic mothers and those in infants of nonanemic mothers either at birth or later.²⁷⁸ Furthermore, iron supplementation during pregnancy has no effect on the subsequent development of iron deficiency in the infant, although it may be protective for the mother. Finally, as measured by serum ferritin levels, maternal iron stores bear no relation to fetal stores.²⁷⁶ These observations are consistent with results of studies in animals that demonstrate iron transported across the placenta against a gradient, even at the expense of maternal iron stores.²⁷⁹

Growth

In the absence of disease, iron requirements of an adult man are relatively low and vary little. In contrast, in infancy, childhood, and adolescence, the requirements for iron are relatively great because of the increased needs of rapidly growing tissues. The most rapid relative growth rates in human development occur in the first year of life. Body weight and blood volume approximately triple, and the circulating hemoglobin mass nearly doubles. Still greater relative growth occurs in premature and low birth-weight infants. Premature infants weighing 1.5 kg may increase their weight and blood volume sixfold and may triple the circulating hemoglobin mass in 1 year. To meet the demands imposed by growth, the normal-term infant must acquire 135 to 200 mg of iron during the first year of life. A premature infant may require as much as 350 mg in the same period.²⁸⁰

The relatively slower rates of growth in children through the remainder of the first decade require a positive iron balance of ~0.2 to 0.3 mg/day. The growth spurt that occurs in the early teens requires a positive balance of ~0.5 mg/day in girls and 0.6 mg/day in boys.¹⁹⁶ Toward the end of this period, the onset of menstruation occurs in girls, and their requirements then equal those of adult women.

Diet in Infancy and Childhood

Iron stores in the infant are typically depleted by 4 to 6 months of age as a result of the demands of growth. During this critical period, a normal full-term infant must absorb ~0.4 to 0.6 mg of iron daily from the diet. To achieve this level of absorption, an iron intake of 1 mg/kg/day is recommended for full-term infants, 2 to 4 mg/kg/day for preterm infants, and at least 6 mg (to a maximum of 15 mg) for preterm infants receiving erythropoietin therapy.²⁸¹ These amounts may be difficult to achieve without supplementation.

Both human milk and cow's milk contain relatively small amounts of iron, but the infant more readily absorbs the iron in P.631

human milk. In one study, 49% of the iron in human breast milk was absorbed, compared with 10% of the iron in cow's milk.²⁸² As a result, iron deficiency is relatively uncommon in the first 6 months of life in infants exclusively fed breast milk.

Formula-fed infants are likely to become iron deficient unless iron-supplemented formulas are used. In the United States, such formulas are often supplemented with iron (10 to 12 mg/L) as ferrous sulfate, of which a variable proportion is absorbed.²⁸¹ Approximately 7% to 12% of the iron in cow's milk-based formulas is absorbed, with the lower percentage seen when formulas with higher iron content are given.²⁸³ Less iron is absorbed from soy-based formulas, but soy formulas containing 12 mg/L of iron appear to be adequate.²⁸⁴ Fortified dry cereals for infants are another important source of iron in the diet of both breast-fed and formula-fed infants. Currently, infant cereals are fortified with small-particle elemental iron at a concentration of 0.45 mg/g, from which ~4% is absorbed.²⁸⁵ Two servings per day will supply the needs of most infants.

Excessive intake of cow's milk is an important cause of iron deficiency in the first 2 years of life.^{280,286} Not only is cow's milk a poor source of iron, it may cause gastrointestinal blood loss (see next section). In general, cow's milk should not be given to infants <1 year of age, although it may be tolerated if the remainder of the diet is iron-rich.²⁸⁷ Some parents allow their toddler children to use the bottle as a pacifier and constant companion, and the children become addicted ("milkaholics"). In one study, inadequate diet was considered the only factor in the development of iron deficiency in 20 of 55 infants²⁸⁸;

few patients in this series had iron deficiency resulting from defective stores at birth, unless the diet was also inadequate. A unique disorder termed Bahima disease, described in Uganda, was attributed to the practice of feeding children a diet of cow's milk almost exclusively.²⁸⁹

Blood Loss in Infancy

Occult hemorrhage, often without obvious anatomic lesions, may be observed in some iron-deficient infants.^{285,290,291} The process is often accompanied by diffuse disease of the bowel with protein-losing enteropathy and impaired absorption of other nutrients.^{292,293} It probably results from hypersensitivity to a heat-labile protein in cow's milk.^{294,295} The daily loss of 1 to 4 ml of blood, along with increased serum albumin turnover, was observed while fresh cow's milk was consumed, and these abnormalities ceased abruptly with the substitution of heat-treated or soybean-protein feeding formulas.

Pregnancy and Lactation

Pregnancy is a major drain on the limited iron reserves of young women. Each pregnancy results in an average loss to the mother of 680 mg of iron, the equivalent of 1,300 ml of blood. An additional 450 mg of iron must be available to support the expanded blood volume during pregnancy. The latter amount of iron does not represent a net loss after delivery because the iron is returned to stores; it must be available. However, during the pregnancy or iron deficiency will supervene.

Prorated over the full term of pregnancy, the iron requirement amounts to ~2.5 mg/day (Table 23.6). Because most of the loss occurs during the third trimester, the requirement is small early in pregnancy and rises to as much as 3.0 to 7.5 mg/day in the third trimester. These amounts are greater than those that can be absorbed from even the best of diets, and stores may be insufficient to meet them. For this reason, iron supplementation is frequently recommended as a component of prenatal care. In the absence of supplements, maternal iron deficiency may occur, usually manifesting in the third trimester.

Lactation results in a daily iron loss of ~0.5 to 1.0 mg. The iron content of human breast milk is probably not affected by the maternal iron stores.²⁹⁶ Because normal menstruation is usually inhibited while breastfeeding continues, iron requirements in the lactating mother approximate those of the menstruating woman.

TABLE 23.6 IRON BALANCE IN PREGNANCY

Iron Fate	Mean Amount (mg)	Range (mg)
Lost to fetus	270	200-370
Lost in placenta, cord	90	30-170
Lost with bleeding at delivery	150	90-310
Normal body iron loss	170	150-200
Added to expanded red blood cell mass	450	200-600
Total	1,130	670-1,650
Returned to stores when red blood cell mass contracts after delivery	450	200-600
Net loss (over 9 months)	680	470-1,050

Signs and Symptoms of Iron Deficiency

The onset of iron deficiency anemia is usually insidious, and the progression of symptoms is gradual. As a result, patients accommodate remarkably well to advancing anemia and may delay a visit to their physicians for prolonged periods.

Fatigue and Other Nonspecific Symptoms

Iron deficiency anemia can be associated with irritability, palpitations, dizziness, breathlessness, headache, and fatigue. Fatigue is a particularly common complaint among patients. Even latent iron deficiency (i.e., iron deficiency without any anemia at all) has been described to result in fatigue,²⁹⁷ but others were unable to confirm this observation.²⁹⁸ Nevertheless, iron therapy has been shown to ameliorate fatigue: a group of 44 nonanemic women reporting fatigue were treated both with iron and with placebo in random order. Symptomatic improvement in women receiving iron was significantly better than that of women given the placebo, but only in women whose iron stores were depleted. In a recent randomized clinical trial of intravenous iron therapy in 90 premenopausal nonanemic women presenting with

fatigue, serum ferritin ≤ 50 ng/ml and Hgb ≥ 12 g/dl, fatigue scores decreased significantly within 6 weeks of therapy compared to placebo, particularly in women with baseline serum ferritin ≤ 15 ng/ml.²⁹⁹

Neuromuscular System

Despite the lack of symptoms at rest, investigators have demonstrated that even mild degrees of iron deficiency anemia impair muscular performance, as measured by standardized exercise tests.^{173, 300} Total exercise time, maximal workload, heart rate, and serum lactate levels after exercise are all affected adversely in proportion to the degree of anemia. Furthermore, work performance and productivity at tasks requiring sustained or prolonged activity are impaired in iron-deficient subjects and improve when iron is administered.^{301,302} As a result, measures directed toward iron nutrition of a workforce can produce important economic dividends, more than offsetting the costs of the treatment program.

Abnormalities in muscle metabolism are noted even when deficiency is mild.³⁰³ Blood lactate levels were measured in mildly

P.632

iron-deficient female athletes after standardized exercise tests. Peak lactate levels fell significantly after 2 weeks of iron treatment. This observation led to the suggestion that iron deficiency forces the muscles to depend to a greater extent on anaerobic metabolism than occurs in normal subjects.

Animal studies demonstrate that muscle function is disturbed in iron deficiency. The spontaneous activity level of iron-deficient rats decreased,³⁰⁴ and short-term exercise tolerance in treadmill running tests was reduced,^{166,167,303,305} even at mild degrees of deficiency.³⁰⁶ These abnormalities could not be explained by anemia alone, because they persisted after anemia was corrected by exchange transfusion.^{166,167} All were corrected promptly when iron was administered. In contrast, in a patient study no abnormalities of muscle function were noted in six nonanemic patients with long-standing iron deficiency, induced for the treatment of polycythemia vera.³⁰⁷

A variety of behavioral disturbances have been observed in iron-deficient children.^{174,308,309,310,311,312} These children have been reported to be irritable and disruptive, with short attention spans and a lack of interest in their surroundings. Neurologic development in infants³¹³ and scholastic performance in older children³¹⁴ may be impaired. Cognitive performance is defective in iron-deficient rats.³¹⁵ All of these behavioral abnormalities are ameliorated with the initiation of iron therapy.

The ability to maintain body temperature on exposure to cold is impaired in iron-deficient patients³¹⁶ and animals.³¹⁷ Occasional patients experience neuralgia pains, vasomotor disturbances, or numbness and tingling. In children, iron deficiency has been associated with neurologic sequelae, including developmental delay, ischemic stroke, increased intracranial pressure, papilledema, and the clinical picture of pseudotumor cerebri.³¹⁸ The pathogenesis is probably complex, involving severe anemia, thrombocytosis, and reduced levels of tissue iron enzymes.

Epithelial Tissues

Patients with long-standing iron deficiency may develop a constellation of symptoms characterized by defective structure or function of epithelial tissues. Especially affected are the nails, the tongue and mouth, the hypopharynx, and the stomach. These epithelial lesions tend to occur together in the same patients at the same time^{319,320} but also may occur as isolated findings.

In iron-deficient subjects, the fingernails may become brittle, fragile, or longitudinally ridged, but these findings are quite nonspecific. Alterations more typical of iron deficiency are nail thinning, flattening, and ultimately the development of koilonychia, concave or "spoon-shaped" nails (Fig. 23.6). Koilonychia is now rarely seen in clinical practice, but of 400 babies attending a wellbaby clinic in West Virginia before 1970, 5.5% had koilonychia, and nearly all of these infants appeared to be iron deficient.³²¹ Koilonychia is a relatively nonspecific finding, which can also result from prolonged repeated exposure to hot soapsuds and other caustic agents.

FIGURE 23.6. Koilonychia in a 1.5-year-old child with iron deficiency anemia.

FIGURE 23.7. Tongue of a patient with iron deficiency anemia. Moderately severe papillary atrophy evident before therapy (A) and restoration after iron repletion (B). (Courtesy of R. W. Monto, Detroit, MI.)

Oral abnormalities, including atrophy of the lingual papillae, are the most common of iron deficiency-induced epithelial changes (Fig. 23.7, Table 23.7). These may present as soreness or burning of the tongue, either spontaneously or stimulated by food or drink, and by varying degrees of redness.³¹⁹ The filiform papillae over the anterior two thirds of the tongue are the first to atrophy and may disappear completely. In severe cases, fungiform papillae also may be affected, leaving the tongue completely smooth and waxy or glistening.³²² These changes are generally reversed after 1 to 2 weeks of iron therapy. Angular stomatitis, characterized by ulcerations or fissures at the corners of the mouth, is a less specific sign of iron deficiency, and it also occurs in riboflavin and pyridoxine deficiencies.

P.633

TABLE 23.7 EPITHELIAL LESIONS ASSOCIATED WITH IRON DEFICIENCY

Site	Finding
Nails	Flattening
	Koilonychia
Tongue	Soreness
	Mild papillary atrophy
	Absence of filiform papillae
Mouth	Angular stomatitis
Hypopharynx	Dysphagia
	Esophageal webs
Stomach	Achlorhydria
	Gastritis

The association of dysphagia, angular stomatitis, and lingual abnormalities with hypochromic anemia was reported as early as the beginning of the 20th century. Dysphagia affects women more often than men and is relatively uncommon in patients younger than age 30 years. However, it has been observed in adolescents^{174,319} and even toddlers. Patients with sideropenic dysphagia (also known as Paterson-Kelly syndrome and Plummer-Vinson syndrome) note a gradual onset of difficulty swallowing and describe discomfort localized to the area of the neck near the cricoid cartilage. They experience dysphagia with solid foods but have little problem with liquids. If not treated, the dysphagia worsens, and ultimately the diet is so restricted that it interferes with the maintenance of balanced nutrition.

The most common anatomic lesion is a “web” of mucosa at the juncture between the hypopharynx and the esophagus.³²³ These webs, which may be multiple, usually extend from the anterior wall into the lumen of the esophagus, but they may encircle the lumen completely, forming a cufflike structure. In some patients, a benign stricture is noted, and the opening into the esophagus at the cricoid area may be reduced to the size of a pinhole or slit. Postcricoid webs may occur in the absence of documented iron deficiency, but nearly all affected patients were iron deficient in one investigative series.³²⁰ Both webs and strictures may be demonstrated by radiographic examination (lateral view) of the neck after barium swallow (Fig. 23.8). Multiple exposures or cineradiography are required for optimal demonstration of these abnormalities.

At biopsy, the webs appear to be constructed of normal epithelium with underlying loose connective tissue, sometimes showing a chronic inflammatory reaction. In a small percentage, hyperchromatic nuclei and increased mitotic activity are observed in the basal cell layer. Biopsy of the strictures demonstrates chronic nonspecific inflammation and degeneration of striated muscle. Carcinoma in the postcricoid area has been noted as a late complication of the syndrome in 4% to 16% of patients.³¹⁹ For relief of the dysphagia, clinicians often must rupture the webs, dilate the stenosis, or both, although treatment with iron supplements relieves dysphagia in mild cases if the associated webs are small.^{324,325}

The variation in the prevalence of sideropenic dysphagia suggests that factors other than iron deficiency may contribute to oroesophageal abnormalities. Genetic factors may be important, as may some unrecognized coexisting nutritional abnormalities.

Immunity and Infection

The relationship between iron deficiency and infection is complex.^{326,327,328} Iron deficiency clearly results in at least two abnormalities in the immune response: defective lymphocytemediated immunity and impaired bacterial killing by phagocytes. Evidence of defective cellular immunity includes as much as a 35% reduction in the number of circulating T cells. Both helper and suppressor T cells are affected.³²⁹ In addition, iron-deficient subjects do not respond as well as normal subjects to certain skin test antigens, such as to *Candida*, diphtheria, and *Trichophyton*. These abnormalities can be corrected by the administration of iron. No abnormalities have been noted in testing with tuberculin or dinitrochlorobenzene. Ribonucleotide reductase is an iron-containing enzyme required for the synthesis of DNA for cell division. Some authors have suggested that reduced levels of this enzyme might lead to impaired ability of the T cells to proliferate, thereby accounting for the defects in cell-mediated immunity, but others have reported changes in cytokine production in iron-deficient patients.

FIGURE 23.8. Esophageal web (arrows) in Plummer-Vinson syndrome.

The nitroblue tetrazolium dye test of phagocyte function yielded abnormal results in iron-deficient children, and the abnormality could be corrected by iron administration.^{330,331} Furthermore, a decrease in the magnitude of the “oxidative burst” accompanying phagocytosis was observed.³³² Finally, killing of several types of pathogenic bacteria by neutrophils was defective.^{330,333}

The sequence of changes in neutrophil function was studied as iron deficiency developed in rats. Myeloperoxidase activity was reduced to a greater extent and responded more slowly to iron therapy than did defects in the oxidative burst.³³⁴

Because the oxidative burst is considerably more important in bacterial killing than is myeloperoxidase, the observations suggest that the neutrophil conserves its most important function as the deficiency develops. The defect in the oxidative burst could be demonstrated only with the use of agents that induced phagocytosis; no defect was noted when the burst was stimulated by soluble agents. Thus, phagocytosis, rather than the oxidative burst itself, may be at fault.

In experiments in an iron-deficient mouse model, lack of hepcidin was responsible for the high inflammatory response to lipopolysaccharide treatment.³³⁵ Taken together, these abnormalities provide a basis for an expectation that resistance to infection may be impaired in iron deficiency. However, a clinically relevant relationship between states of iron deficiency and susceptibility

P.634

to infections remains controversial.³³⁶ Conversely, considerable data suggest that iron deficiency and iron sequestration by binding proteins protect against infection by depriving the invading organisms of the metal.^{337,338} Thus, optimal immune function is highly dependent on iron balance; both iron-deficient and iron overloaded hosts are at higher risk for infection.

Pica

Pica is a striking symptom of iron deficiency. Hippocrates wrote that a "craving to eat earth" was associated with "corruption of the blood." Abnormal eating patterns were also a prominent manifestation of chlorosis. Pagophagia, defined as the purposeful eating of at least one tray of ice daily for 2 months, is a common form of pica. In one study, the ingestion of ice averaged nearly 2 kg/day, and some patients ate an astounding 4 to 9 kg/day.³³⁹ This dramatic symptom was relieved within 1 to 14 days after iron was administered. Another study found that pagophagia was a symptom of iron deficiency in 23 of 38 consecutive adult patients, and iron therapy was curative.³⁴⁰ Pica is especially striking when the patient consumes bizarre, nonfood substances.³⁴¹

Crosby estimated the incidence of pica in his iron-deficient patients to be 50%.³⁴² Approximately one half of them ate ice; the rest experienced "food pica." The latter consists of compulsively eating one food, often something that is brittle and makes a crunching sound when chewed.³⁴³ Because patients may be ashamed of this compulsive habit, they often do not volunteer the information during the medical interview. Direct tactful inquiry is necessary to elicit the history of pica.

Genitourinary System

Disturbances in menstruation are common in iron deficiency, and not infrequently, iron deficiency results from, or is exacerbated by, excessive menstrual blood loss. Beeturia, the excretion of a pink to red pigment in the urine after the ingestion of beets, has been reported to be more common in iron-deficient patients than in normal subjects.³⁴⁴ However, it is likely that a significant fraction of the normal population also has this symptom.³⁴⁵

Skeletal System

Changes in the skull similar to those found in association with thalassemia or chronic hemolytic anemia have been reported in children with iron deficiency anemia of long duration.^{346,347} The diploic spaces may be widened, and the outer tables thinned, at times with vertical striations producing a hair-on-end appearance. In addition, abnormalities of the long bones are noted, especially the metacarpals and phalanges, with expansion of the medulla and thinning of the cortices.³⁴⁸ These changes likely result from expansion of the erythroid marrow during bone growth and development.

LABORATORY EVALUATION

Complete Blood Count and Peripheral Smear

The severity of anemia depends on the presenting circumstances of iron deficiency. If discovered when the patient is being evaluated for preadmission testing for elective surgery (Fig. 23.9),³⁴⁸ or for an underlying or unrelated disease, the anemia can be mild to moderate (Hgb 8 g/dl to 12 g/dl). If symptoms of anemia are the presenting complaint, the blood hemoglobin level may be 8 g/dl or lower.

Anisocytosis is an important early sign in iron deficiency and one that has differential diagnostic value when quantified.^{349,350} The red cell distribution width (RDW) is increased in iron deficiency, and this often is useful in distinguishing iron deficiency from thalassemia trait conditions in which the RDW is normal. Both the percentage and the absolute number of reticulocytes may be normal or slightly increased. In experimentally induced iron deficiency in certain animal species, including rats, mice, and pigs, reticulocytosis is pronounced. The chief finding on blood smear is

hypochromia, observed as an increase in the size of the region of central pallor (Fig. 23.10). The more severe the anemia, the more severe the hypochromia and the greater the percentage of erythrocytes affected. When hypochromia is extreme, most of the red blood cells appear as mere rings. Tiny microcytes and a moderate number of poikilocytes, particularly tailed and elongated elliptical forms (pencil cells), are also found. In almost all instances, however, a variable number of well-filled red corpuscles are present, and some macrocytes, often polychromatophilic, can be distinguished. The mean corpuscular volume and mean corpuscular hemoglobin values are reduced in most patients, and the mean corpuscular hemoglobin concentration is reduced in long-standing or severe disease. The degree of change in the red cell indices is related in part to the duration and in part to the severity of the anemia. In mild iron deficiency of short duration, the indices may be within normal ranges.

Iron-related Indices

The laboratory diagnosis of absolute iron deficiency has traditionally been based on low serum iron, low percent transferrin saturation, and low ferritin.¹⁴³ However, it has long been known that inflammation can mimic some aspects of iron deficiency by impairing the utilization of existing iron stores for red cell production, and inducing an iron-sequestration syndrome and hypoferrremia.³⁵¹ The molecular mechanisms that underlie the redistribution of iron during inflammation are discussed in Chapter 45, but may center on cytokine-stimulated overproduction of hepcidin, particularly IL-6.³⁶

Serum ferritin has the potential to differentiate true iron deficiency from inflammatory iron sequestration. However, both inflammation and intracellular iron accumulation stimulate the production of the iron storage protein ferritin whose soluble form is detectable in plasma and serum. Therefore, interpretation of serum ferritin in patients with inflammation due to comorbidities is more challenging. The generally accepted cut-off level for serum ferritin to indicate absolute iron deficiency has been ≤ 12 ng/ml.³⁵² However, studies correlating the presence or absence of stainable iron with serum ferritin in patients and in normal individuals, and also patients with anemia responsive to iron therapy, indicate that this threshold level of ferritin had only a sensitivity of 25% for detecting iron deficiency.³⁵³ The sensitivity could be improved to 92%, with a positive predictive value of 83%, by using a diagnostic cutoff value of ≤ 30 ng/ml.

The differentiation among absolute iron deficiency, functional iron deficiency, and iron-sequestration syndromes (Fig. 23.11) is important for patient management.²⁶⁸ Functional iron deficiency is manifest by a fall in iron saturation either during endogenous erythropoietin-stimulated erythropoiesis,^{268,354,355} or with initiation of ESA therapy even in normal volunteers with adequate iron stores.^{268,356} The manifestation of functional iron deficiency is reduced transferrin saturation, as illustrated in Figure 23.12. Absolute iron deficiency may be the presenting sign of occult blood loss from gastrointestinal lesions including malignancy,^{233,357} whereas an iron sequestration phenotype is indicative of an underlying inflammatory disorder. Commonly used laboratory tests such as serum iron, total iron-binding capacity, mean corpuscular volume, transferrin saturation, and ferritin provide limited diagnostic value.^{127,358}

Increased soluble transferrin receptor (sTfR) has been reported to be an indicator of iron deficiency,³⁵⁹ because sTfR is released

P.635

P.636

by erythropoietic precursors in proportion to their expansion, and is not increased by inflammation. However, this assay was found to have a specificity of 84% and a positive predictive value of only 58% in a population of patients likely to be typical of the most difficult diagnostic environments for assessing iron status.³⁵³ Interpretation of increased sTfR therefore may be challenging, even in the absence of known causes of increased erythropoiesis other than iron deficiency. Similarly, attempts to combine ferritin and sTfR results (sTfR/log ferritin)³⁶⁰ still fall short when analyzed for diagnostic sensitivity and specificity, and must be corrected for acute phase reactant changes in the setting of inflammation.³⁵⁸

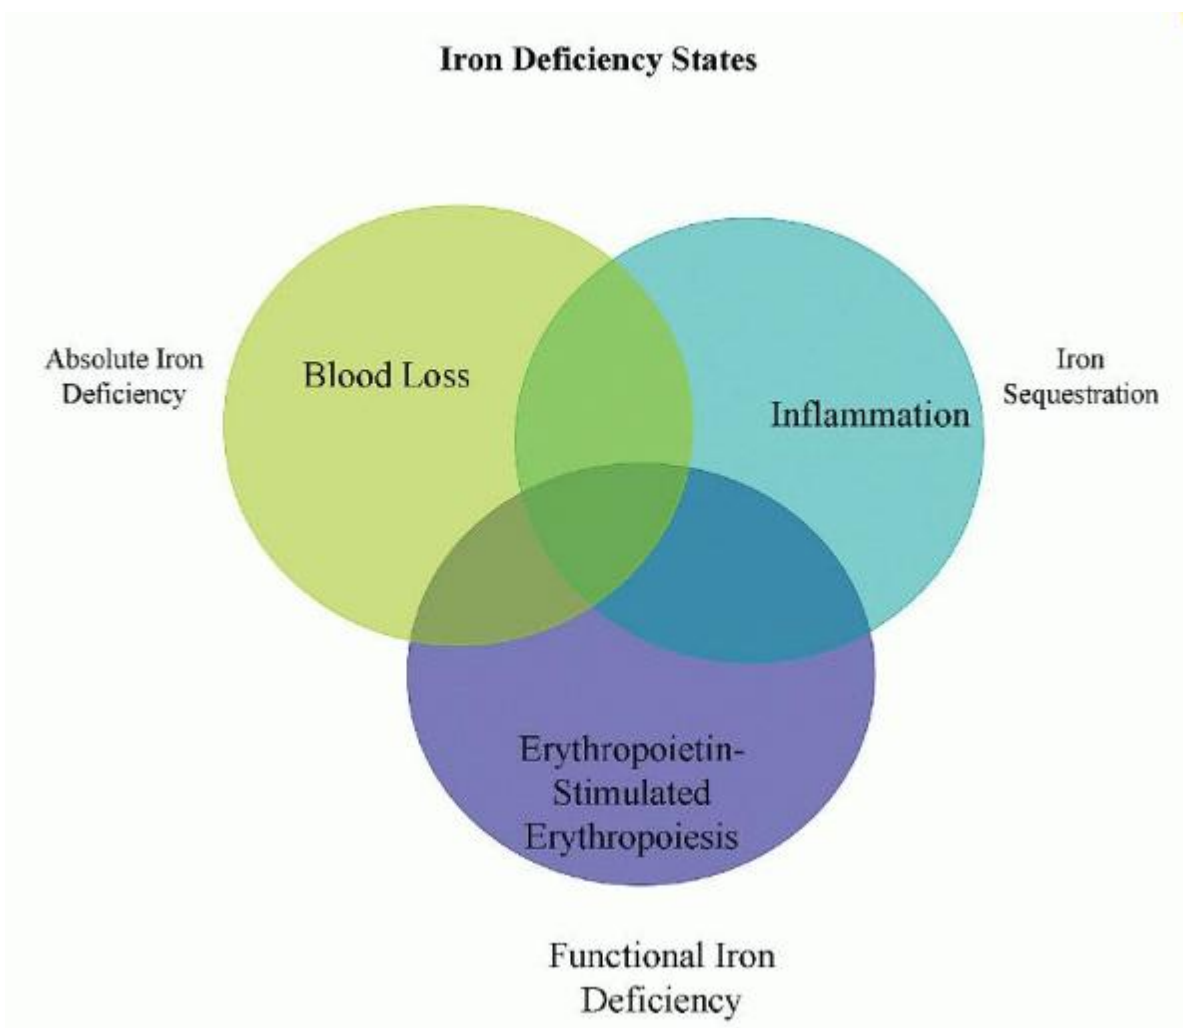

FIGURE 23.11. Iron deficiency states. The relationships between absolute iron deficiency, iron sequestration, and functional iron deficiency are illustrated. Patients can have one or more combinations that all result in iron-restricted erythropoiesis. (From Goodnough LT. Transfusion. 2011 Dec 12 [Epub].)

FIGURE 23.12. The impact of endogenous erythropoietin-mediated erythropoiesis or ESA (erythropoiesis stimulating agent) mediated erythropoiesis, on iron saturation. Patients undergoing autologous blood donation prior to elective

orthopedic surgery are shown at baseline and after treatment with placebo or one of two doses of recombinant human erythropoietin (rHuEPO) at each visit during the donation period. All patients received supplemental oral iron. Mean transferrin saturation in 24 patients receiving placebo (Δ), 300 U per kg rHuEPO (Z), or 600 U per kg rHuEPO (θ). (From Mercuriali F, Zanella A, Barosi G, et al. Use of erythropoietin to increase the volume of autologous blood donated by orthopedic patients. *Transfusion* 1993;33:55-60.)

The development of sensitive, accurate, and reproducible immunoassays^{43,361} and mass-spectrometric assays³⁶² for human hepcidin has allowed detailed definition of physiologic and pathologic changes of hepcidin in healthy volunteers and in patients. In contrast to ferritin, changes in hepcidin concentrations are frequently the cause of, rather than the result of, iron disorders. Measurements of hepcidin may be useful for diagnosing absolute iron deficiency or differentiating it from iron-sequestration syndromes. In absolute iron deficiency, serum hepcidin concentrations are very low.⁴³ Low hepcidin would also identify patients most likely to respond to iron therapy. In iron sequestration syndromes, on the other hand, hepcidin would be expected to be high as the pathogenic mediator of iron restriction in inflammation. In patients with mixed presentations, hepcidin may be regulated by opposing stimuli and its levels tend to be variable.³⁶³ For example, in conditions with mixed iron deficiency and inflammation, hepcidin may be low, normal, or elevated depending on the degree of iron deficiency or inflammation. In resistance to ESA therapy due to chronic kidney disease, hepcidin levels may be high because of decreased hepcidin renal clearance and possibly inflammation. In the absence of inflammation, in conditions of accelerated erythropoiesis due to endogenous erythropoietin or ESA stimulation, hepcidin levels will be low. Thus in patients with mixed conditions, hepcidin levels may not help treating physicians arrive at a definitive diagnosis but may give guidance in identifying patients who are likely to respond to iron (oral vs. IV) therapy (i.e., hepcidin levels are low with marginal storage iron or accelerated erythropoiesis). More complex algorithms will need to be developed and tested to provide optimal guidance in the evaluation and management of anemia.^{86,364} Expected changes in hepcidin levels and iron parameters in various clinical conditions, in iron therapy strategies, and in the potential use of hepcidin-targeted therapies in patients with various forms of anemia, are summarized in Table 23.8.

TABLE 23.8 POTENTIAL ROLE OF HEPCIDIN IN DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH IRON-RESTRICTED ERYTHROPOIESIS

Condition	Expected Hepcidin Levels	Iron Parameters	Iron Therapy Strategies	Potential Hepcidin Therapy
Absolute iron deficiency anemia (IDA)	Low	Low TSAT and ferritin	PO or IV if poorly tolerated or malabsorbed	No
Functional iron deficiency (ESA therapy, CKD)	Variable, depending on \pm CKD	Low TSAT, variable ferritin	IV	Antagonist (if hepcidin levels not low)
Iron sequestration (anemia of inflammation [AI])	High Low TSAT, normal-to-elevated ferritin	IV	Antagonist	
Mixed anemia (AI/IDA) or (AI/functional iron deficiency)	Variable	Low TSAT, low-to-normal ferritin	IV ^a	Antagonist (if hepcidin levels not low)

^aMixed anemia is a diagnosis of exclusion without a therapeutic trial of iron.

CKD, chronic kidney disease; ESA, erythropoiesis-stimulating agent; IV, intravenous; PO, oral; TSAT, transferrin saturation.

From Goodnough LT. Iron deficiency syndromes and iron-restricted erythropoiesis. *Transfusion*. 2011 Dec 29 [Epub].

Clinically, it would be helpful to detect the earliest changes in red cell indices that reflect iron-restricted erythropoiesis. One approach would be to identify newly formed iron-deficient cells when they are released from the bone marrow as reticulocytes. Flow cytometric analysis of reticulocytes allows determination of reticulocyte hemoglobin content

(CHr)^{365,366} or percentage of hypochromic reticulocytes (% HYPO).³⁶⁷ As illustrated in Figure 23.13, this approach can also identify functional iron deficiency in iron-replete volunteers receiving ESA therapy.³⁶⁸ The % HYPO measure is regarded as a time-averaged marker of iron-restricted erythropoiesis (20 to 120 day), whereas the CHr measure is a real-time parameter (48 hours).³⁶⁹ Many existing laboratory analyzers are capable of measuring CHr but may require modification with software patches.

Leukocytes and Platelets

The leukocytes are usually normal in number, but mild granulocytopenia may occur in long-standing cases of iron deficiency. Recent large-volume hemorrhage may cause a slight neutrophilic leukocytosis, and occasional myelocytes may be found in peripheral blood. In iron deficiency due to parasitic infestation, eosinophilia may be present.

Thrombocytosis commonly accompanies iron deficiency.³⁷⁰ The platelet count often increases to approximately twice the normal level, and values return to normal after iron therapy. The cause of the thrombocytosis of iron deficiency is unknown.

(From Goodnough LT, Nemeth E, Ganz T. Detection, evaluation, and management of iron-restricted erythropoiesis. *Blood* 2010;116:4754-4761.)

Bone Marrow

Macrophage iron is absent or severely reduced in the marrow, spleen, and liver of iron-deficient subjects. Fewer than 10% of the marrow normoblasts are sideroblasts. In addition, the iron-deficient bone marrow is characterized by mild to moderate erythroid hyperplasia. There may be striking nuclear distortions, resembling those found in dyserythropoietic anemias.³⁷¹ Karyorrhexis and nuclear budding are particularly common, but multinuclearity, nuclear fragmentation, and even intranuclear bridging may be observed. The individual normoblasts appear small and may have scanty cytoplasm,

often with irregular ragged borders. When therapy is given, erythroid hyperplasia initially increases, but as erythropoiesis is restored to normal, the cellularity of the marrow likewise becomes normal.

MANAGEMENT OF IRON DEFICIENCY

Management is primarily focused on repletion of iron stores. Most of the time, this therapy is straightforward, simple, and inexpensive. The response to treatment is predictable and gratifying. There is, however, an important caveat: correction of the iron deficiency is only part of the task confronting the clinician. Particularly in older adults, iron deficiency may be an early sign of a serious illness, such as an occult gastrointestinal malignancy. Clearly, correction of the anemia without recognition and treatment of a possible underlying disease is poorly practiced medicine. The cause of iron deficiency anemia can be identified in the great majority of cases. Once an etiologic diagnosis is made, appropriate therapy can begin.

Iron can be administered orally or intravenously. The oral route is the safest and least expensive. It is important to note that therapeutic doses are quite different for oral and intravenous preparations. Most iron-deficient patients respond well to oral therapy, but intravenous administration of iron may sometimes be required.

Oral Iron Therapy

The most common preparation used orally is ferrous sulfate, which has been a mainstay of treatment for iron deficiency since it was first introduced by the French physician Pierre Bland in the 19th century. It is effective, reasonably well tolerated, and inexpensive. If equivalent amounts of elemental iron are given, ferrous gluconate and ferrous fumarate are equally satisfactory and have approximately the same incidence of side effects. Although iron deficiency clearly promotes increased absorption, individual variations are great, and absorption may be vastly different at varying degrees of anemia and in the presence of complicating illnesses.

The dose is best calculated in terms of elemental iron. For adults, the optimal response occurs when ~200 mg of elemental iron is given orally each day. The usual ferrous sulfate tablet (325 mg) contains ~65 mg of elemental iron. Iron is absorbed more completely when the stomach is empty; when iron ingestion occurs after or with a meal, absorption decreases substantially.³⁷² However, gastrointestinal irritation is common when the stomach is empty. Consequently, patients are frequently advised to take oral iron immediately after or even with a meal. The gain in patient acceptance may be more important than the reduced absorption of iron. However, it is important to remember that, whereas absorption is enhanced by the presence of orange juice, meat, poultry, and fish, other substances such as cereals, tea, and milk inhibit it. This is particularly important in toddlers, because administration of oral iron with milk often compromises therapy.

For iron-deficient children, the optimal dosage is 1.5 to 2.0 mg elemental iron per kilogram of body weight given orally three times per day. Palatable elixirs and syrups are the most satisfactory pediatric preparations, although they can stain the teeth if not given carefully. Children usually tolerate this form of therapy on an empty stomach.

In adults, a 200-mg daily oral dose produces a maximal rate of hemoglobin regeneration. However, the maximal rate is not necessarily the only legitimate therapeutic goal. If the underlying disease has been corrected and the anemia is mild to moderate, a slower rate of response may be acceptable. Thus, if such patients cannot tolerate 200 mg/day of elemental iron, it is reasonable to reduce the dose to 100 mg/day.³⁷³ Because less iron is given, tolerance improves. In this circumstance, speed of response is exchanged for increased patient compliance, although it may be necessary to treat for longer. Regardless of the form of oral therapy used, treatment should be continued for at least 3 to 6 months after the anemia is relieved. If treatment does not continue, relapse is common. The continued therapy allows for repletion of iron stores.

Side Effects of Oral Iron Therapy

Some patients given oral iron report gastrointestinal symptoms, including heartburn, nausea, abdominal cramps, and diarrhea. However, functional gastrointestinal symptoms are common in the general population, and patients may incorrectly ascribe them to iron treatment. In one double-blind study, ferrous sulfate, ferrous gluconate, ferrous fumarate, and placebo were administered in identically appearing tablets.³⁷⁴ No significant differences were found among the three iron salts. Approximately 12% of subjects had symptoms that could reasonably be ascribed to iron ingestion. Often, tolerance of iron salts improves when a small dose is given at first and increased over the course of several days to the full dose. A polysaccharide-iron complex is marketed that is alleged to be as effective as ferrous sulfate while causing fewer side effects. The question of whether it is as well absorbed as ferrous sulfate has not been definitively resolved.

Enteric-coated preparations are designed to reduce side effects by retarding dissolution of the iron. However, this effect may markedly decrease absorption, especially in achlorhydric individuals, whose gastric juice cannot dissolve the coating.

Sustained-release preparations also reduce side effects by retarding dissolution, but in so doing, the most actively absorbing regions of the intestine are bypassed. According to most studies,³⁷⁵ absorption is therefore reduced.

P.638

Failure of Oral Iron Therapy

Clinicians often encounter patients said to have iron deficiency anemia unresponsive to oral therapy. The most common explanations for failure to respond to oral iron include (a) incorrect diagnosis, (b) complicating illness, (c) failure of the patient to take prescribed medication, (d) inadequate prescription (dose or form), (e) continuing iron loss in excess of intake, and (f) malabsorption of iron.

In managing a problem of alleged failure to respond to iron, it is important to review the data on which the diagnosis of iron deficiency anemia was based and to take note of any laboratory procedures that might have yielded erroneous information. At times, even though iron deficiency is present, a coexisting cause for anemia may impair response. Examples are iron deficiency as a complication of the anemia of inflammation in rheumatoid arthritis, *H. pylori* infection, as well as so-called dimorphic anemia, in which iron deficiency and pernicious anemia coexist.

In some patients, blood loss is so great that oral iron therapy cannot keep up with it. If this situation is not correctable (e.g., in the case of hereditary hemorrhagic telangiectasia), parenteral therapy must be given. Finally, rare patients may be unable to absorb iron. This is unusual; even patients with sprue or total gastrectomy are usually able to absorb adequate amounts of ferrous sulfate. Patients with iron-refractory iron deficiency syndrome (IRIDA) have a mutation in the protease TMPRSS6 causing increased hepcidin production^{177,178,189,190} and are refractory to oral iron therapy but partially responsive to intravenous iron therapy.

In individuals who are compliant with oral therapy and not actively bleeding, but still poorly responsive to treatment, addition of ascorbic acid (usually 500 mg twice a day) may improve iron absorption and the hemoglobin response.^{376,377} and³⁷⁸ Subclinical ascorbic acid deficiency has been suggested as an etiology of refractory iron deficiency anemia.³⁷⁹

Even under the best of circumstances, oral iron supplementation is poorly tolerated and patients may be noncompliant, not only from side effects of oral iron but because of their diagnosis or the therapy they are undergoing for their disease. Nevertheless, in stable patients with mild to moderate anemia in which there is some time for management strategies, and particularly in those patients in whom diagnostic laboratory testing has not definitively ruled out iron-restricted erythropoiesis, a therapeutic trial of oral iron therapy can be recommended.³⁸⁰ In general, absorption of oral iron inversely correlates with hepcidin levels.^{381,382} Thus, hepcidin measurements may help to determine a priori which patients are good candidates for oral iron therapy. Exceptions may be patients who malabsorb iron because of damage to the intestinal lining such as in celiac disease, and in patients undergoing treatment with proton-pump inhibitors.

In a study of patients with anemia,³⁵³ 5 of 54 who had bone marrow examinations had absent iron stores indicating absolute iron deficiency. There were an additional eight patients who were categorized as iron deficient because of their response to oral iron therapy; half of these had serum ferritins ≥ 12 ng/ml and one of the patients had a serum ferritin >100 ng/ml. This analysis suggests that in the absence of a diagnostic bone marrow examination, it is difficult to rule out iron deficiency confidently, and an empiric trial of iron therapy may be desirable to identify patients who have absolute iron deficiency for successful patient management, because it may be a sign of serious underlying illness,^{231,383} including malignancy.^{233,357}

Failure to respond to a trial of oral iron therapy does not rule out iron-restricted erythropoiesis or even true iron deficiency in the setting of inflammation, as inflammatory hepcidin elevation would cause impaired iron absorption.³⁶ Furthermore, ongoing blood (and iron) losses may exceed even maximal gastrointestinal absorption of iron.³⁸⁴ Clinical situations are often complex, and blood loss, iron-restricted erythropoiesis and high hepcidin levels can coexist in patients in whom absorption of dietary or oral iron supplements is impaired.³⁶⁴ In these instances, and in circumstances of ongoing blood loss,³⁸⁴ intravenous iron therapy may be needed either as a diagnostic trial or as definitive therapy.³⁸⁵

Intravenous Iron Therapy

Therapy with ESAs in management of the anemia of chronic renal failure has led to substantial clinical experience in supplemental intravenous iron therapy in this setting.^{386,387} Hyporesponsiveness to ESA therapy is a common phenomenon^{388,389} due to a variety of comorbid conditions, but particularly related to functional iron deficiency.^{354,356} Patients with anemia undergoing dialysis may show suboptimal or no response to oral iron therapy for several reasons.

During ESA therapy, although absorption of iron can increase up to fivefold³⁹⁰ presumably due to hepcidin suppression by increased erythropoiesis, ongoing external iron losses due to hemodialysis and blood testing can exceed the intake.^{391,392} Furthermore, some patients have poor compliance with iron therapy or significantly reduced gastrointestinal iron absorption. Absorption of oral iron can be enhanced with ascorbate by at least 30%, because it prevents formation of insoluble and unabsorbable compound and reduces ferric iron to ferrous iron.³⁹² Iron absorption and release from stores may be impaired due to high hepcidin levels from diminished clearance by the kidneys, not completely corrected by routine hemodialysis, as well as from inflammation.

IV iron administration is recommended in renal dialysis patients undergoing ESA therapy.³⁹³ Patients treated with IV iron (100 mg twice weekly) achieved a 46% reduction in ESA dosage required to maintain hematocrit (Hct) levels between 30% and 34%, compared to patients supplemented with oral iron.³⁹⁴ To further address the management of iron-restricted erythropoiesis in CKD patients undergoing dialysis, a randomized controlled trial evaluated the efficacy of IV iron supplementation in patients with ferritin between 500 and 1,200 ng/ml.³⁹⁵ The administration of IV iron (and increasing the dose of ESA by 25%) resulted in a greater correction of anemia compared with increasing the dose of ESA alone. After the end of the trial, there was greater success in reducing the dose of ESA in the patients receiving IV iron, compared to the non-iron-treated arm.

IV iron therapy also improves responses to ESA therapy in patients with inflammatory bowel disease³⁹⁶ compared to responses in a similar patient group who received oral iron supplementation.³⁹⁷ Decreased reticulocyte hemoglobin (CHr) is an indicator of the inadequacy of iron supply in the face of increased iron demand stimulated by ESA therapy.³⁵⁹ The requirement for a kinetic balance between iron delivery and level of erythropoietin stimulation may explain the need for intravenous iron supplemental therapy in ESA-treated patients, even those with replete iron stores.³⁹³ The clinical response to the combination of IV iron and ESA therapy may be attributed to the ability of the parenteral route to circumvent the inflammation-induced block to intestinal iron absorption and deliver a large dose of iron to the reticuloendothelial system, which could increase iron efflux from macrophages, perhaps by increasing the translation of ferroportin mRNA.

Currently approved intravenous iron preparations are listed in Table 23.9.³⁹⁸ The risk-benefit profile of IV iron continues to undergo evaluation in renal dialysis patients,^{393,399} as well as in patients with anemia of chronic diseases.¹²⁷ IV iron can allow up to a fivefold greater erythropoietic response to significant blood loss anemia in normal individuals.^{400,401} A greater rate of red cell production is probably not possible unless red marrow expands into yellow marrow space, as is seen in patients with hereditary anemias.^{402,403} One potential limitation to IV iron therapy may be that much of the administered iron ends up in

P.639

the reticuloendothelial system as storage iron, from where it is not readily available for erythropoiesis,⁴⁰³ particularly if hepcidin concentrations are elevated. However, for patients with iron deficiency, 50% of IV iron is incorporated into hemoglobin within 3 to 4 weeks.⁴⁰⁴ For patients with anemia of chronic disease or renal failure, IV iron is mobilized less rapidly from the reticuloendothelial system.⁴⁰⁵ Nevertheless, when iron dextran was given intravenously to patients with the anemia of rheumatoid arthritis, cellular hemoglobin concentrations increased significantly.⁴⁰⁶

From Goodnough LT, Shander AS. Current status of pharmacologic therapies in patient blood management. *Anesth Analg* 2012; in press.

In patients with malignancy and chemotherapy-induced anemia, five trials have studied IV iron in the setting of therapy with ESAs. In one study⁴⁰⁷ of patients undergoing chemotherapy, 155 patients were treated with ESA and randomized to receive either no iron; oral iron as 325 mg of ferrous sulfate twice daily; 100-mg boluses of IV iron dextran weekly until the total calculated iron deficit was administered; or a single of IV iron dextran to the same calculated dose. There were significant improvements in hemoglobin levels and hematopoietic responses in both patient groups treated with IV iron arms, compared to those receiving oral iron or no iron therapy.

Another study⁴⁰⁸ assigned 189 patients to receive ESA weekly plus no iron, oral iron as 325 mg of ferrous sulfate thrice daily, or IV ferrous gluconate as 125 mg weekly boluses. The cohort treated with IV iron had improved hemoglobin and hematopoietic responses compared to the other cohorts. A third study⁴⁰⁹ randomly assigned 67 patients with lymphoproliferative malignancies not receiving chemotherapy with IV or no iron. Again, IV iron resulted in improved hemoglobin and hematopoietic responses. A fourth study of 398 patients with chemotherapy-induced anemia who were treated with ESA therapy, found significant improvement in hemoglobin levels and hematopoietic responses in the patient cohort treated with IV iron,⁴¹⁰ further confirmed by a fifth study.⁴¹¹

Iron-restricted erythropoiesis has been shown to be a consideration at time of cancer diagnosis even before ESA therapy: 17% of carefully screened patients were found to have serum ferritins <100 ng/ml and 59% had transferrin saturations (TSAT) less than 20% at diagnosis.⁴¹² Additionally, renewed attention has been placed on the dose-response relationship between ESA dosage and red cell production responses in ESA-treated patients. Once ESA therapy is administered, even subjects with normal baseline levels develop TSAT and ferritin decreases to levels indicating iron-restricted erythropoiesis.^{354,356} Accordingly, guidelines by the National Comprehensive Cancer Network (NCCN) have recommended that iron studies be obtained at baseline in order to identify patients who are candidates for supplemental iron therapy, and that if subsequent hemoglobin levels after 4 weeks of ESA therapy indicate no response (<1 g/dl increase in hemoglobin), then IV iron supplemental therapy should be considered, along with an increase in ESA dose.⁴¹³

Despite these beneficial effects in treatment of iron deficiency, intravenous iron administration may generate oxidative stress and other inflammatory changes.³⁹³ A mouse model showed that red cell transfusion of aged blood resulted in oxidative stress and inflammatory cytokine secretion in response to macrophage-ingested iron from membrane-encapsulated hemoglobin, but not from stroma-free lysate derived from stored red cells.⁴¹⁴ Long-term effects of the intravenous iron preparations will require careful study in relevant clinical settings.^{327,415}

The hypoferrremia and anemia of inflammation can be viewed as a mechanism of defense against providing iron to unwanted pathogens,⁴¹⁶ and therefore adaptive. On the other hand, others are not convinced that iron deficiency or iron-restrictive anemia should be regarded as a desirable condition that benefits patients with infection or inflammation. Although more evidence is clearly needed, in patients who show symptoms attributable to moderate or severe anemia of inflammation, and who do not suffer from overwhelming or difficult to control infection, iron-restricted erythropoiesis can and should be treated, an argument that is not new.³⁷³ In iron-restricted anemias other than absolute iron deficiency, the optimal treatment is still evolving and may be improved by the ongoing development of hepcidin-targeted therapies.

Important clinical subjects for further study in this area should include improving the diagnosis of various forms of iron-restricted anemia in complex clinical settings, testing optimal combinations of ESA and IV iron treatments, analysis of the relative risk-benefits of ESA and IV iron therapy, and the appropriate

P.640

use of adjuncts such as anti-inflammatory therapy or frequent dialysis. Basic scientific insights that could facilitate the progress in this area include understanding the molecular nature of the erythropoietic iron regulator and suppressor of hepcidin, details of the mechanisms by which circulating and stored iron regulates hepcidin, the contribution of hepcidin-independent mechanisms to anemia of inflammation, and the role of genetics in sporadic iron deficiency.

Side Effects of Parenteral Iron Therapy

Side effects may be local or systemic. With intravenous injection, rates of administration greater than 100 mg/minute are associated with pain in the vein injected, flushing, and a metallic taste.⁴¹⁷ Such reactions are brief in duration and relieved immediately by slowing the injection. Systemic reactions may be either immediate or delayed. Immediate side effects include hypotension, headache, malaise, urticaria, nausea, and rare anaphylactoid reactions, particularly to iron dextran. Delayed reactions include lymphadenopathy, myalgia, arthralgia, and fever. Most of the reactions are mild and transient, but the anaphylactoid reactions may be life-threatening.^{417,418} For iron dextran therapy, the clinician should be prepared for the possibility of anaphylaxis by having epinephrine, oxygen, and facilities for resuscitation available. Sodium ferric gluconate, iron sucrose, and iron saccharates are generally better tolerated than the iron-dextran complex, as long as the recommended dosages are not exceeded.^{143,385}

Response to Therapy

When specific iron therapy is given, patients often show rapid subjective improvement, with disappearance or marked diminution of fatigue, lassitude, and other nonspecific symptoms. This response may occur before any improvement in anemia is observed. Similarly, pica has been reported to be relieved within 1 week of therapy.³³⁹

The earliest hematologic evidence of response to treatment is an increase in the percentage of reticulocytes and their hemoglobin content. The reticulocytes attain a maximal value on the fifth to tenth day after institution of therapy and thereafter gradually return to normal. The maximal value usually ranges from 5% to 10% and is inversely related to the level of hemoglobin. The reticulocyte response may not be detectable in mild iron deficiency anemia.

The blood hemoglobin level is the most accurate measure of the degree of anemia in iron deficiency. During the response to therapy, the red cell count may increase temporarily to values above normal, but the hemoglobin value lags behind. The red cell indices may remain abnormal for some time after the normal hemoglobin level is restored. As recovery occurs, a normocytic cell population gradually replaces the microcytic cell population, and one of the early signs of response to therapy is an increase in the RDW from pretreatment levels. When treatment is fully effective, hemoglobin reaches normal levels by 2 months after therapy is initiated, regardless of starting values.

Of the epithelial lesions in iron deficiency, those affecting the tongue and nails are the most responsive to treatment. After 1 to 2 weeks, small regenerating filiform papillae are observed. After 3 months, the tongue has usually returned to normal; however, in patients with severe anemia, some atrophy may persist. Koilonychia usually disappears in 3 to 6 months, with the concavity moving toward the end of the nail as the nail grows. Gastritis and the associated defects in gastric secretion often do not respond to therapy, especially in older adults. In patients younger than 30 years of age, gastric acid secretion and normal epithelial architecture may be restored.²¹⁵

Dysphagia may be relieved by iron therapy if the associated postcricoid webs are small or medium sized.³²⁴ The webs themselves are not altered, however, and relapse of the anemia is associated with recurring dysphagia. With more severe lesions, dilatation of the esophagus is required for relief.

Relapse occurs in a significant fraction of patients who respond to iron treatment, in part because of failure to complete the full course of therapy and in part because of recurrence (or continuation) of the predisposing condition or illness.

Preventive Treatment

Certain people are at such high risk for developing iron deficiency that prophylactic measures may be considered. These include infants, pregnant women, adolescents, regular blood donors, women with menorrhagia, and patients receiving continuous, high-dose aspirin therapy. Iron supplementation has been recommended for pregnant women for almost half a century. Although the advantages of this practice have not been definitively established,^{419,420} the large iron cost of pregnancy and delivery to the mother (Table 23.6) indicate that it is warranted, evidenced by recommendations by the US preventative services task force that pregnant women be screened for iron deficiency.²¹¹

In 1999, the Committee on Nutrition of the American Academy of Pediatrics made recommendations for iron supplementation in infants.²⁸¹ They suggest that breastfeeding is preferable for the first 5 to 6 months of life if it is feasible, and beyond 6 months of age, breast-fed infants should receive supplemental iron at 1 mg/kg/day. Infants who are not breast-fed should be given formula supplemented with 12 mg/L of iron through the first year of life. The Committee recommends using iron-fortified cereal at the time that a solid diet is begun. Finally, fresh cow's milk should be avoided until after the first birthday.

Recovery from Anemia after Acute Hemorrhage

Morphologic evidence of active red cell regeneration should disappear after 10 to 14 days, if hemorrhage does not recur. The leukocyte count should be normal after 3 to 4 days. Sustained reticulocytosis is suggestive of continued bleeding. Persistent leukocytosis may result from the same cause, from hemorrhage into body cavities, or from complications. The latter, particularly infections, tend to delay the hematopoietic response.

Acute Iron Intoxication

The accidental ingestion of iron compounds by children who have mistaken the tablets for candy is a common problem, particularly with toddlers whose mothers are taking iron-containing prenatal vitamin supplements.^{421,422} and ⁴²³ A few cases have also been reported in adults.⁴²⁴ At one time, the associated mortality rate was as high as 50%. Those persons who died had swallowed 3 to 10 g or more.

Symptoms of iron intoxication have been classified in four stages. In the first stage, gastrointestinal symptoms predominate (vomiting, diarrhea, and melena). Shock may ensue, followed by dyspnea, lethargy, and coma. These events occur in the first 6 hours after ingestion. In the second stage, lasting from 6 to 24 hours after ingestion, transient improvement occurs and may continue to recovery. In stage three, metabolic acidosis is present. Death may take place 12 to 48 hours after ingestion. Stage four consists of intestinal obstruction as a late complication caused by scarring of the intestine.

These ill effects are the consequence of the local irritative action of the iron, resulting in mucosal ulceration and bleeding. Capillary dilatation and diapedesis of red cells may occur. Many factors cause the shock, including the absorption of iron in amounts far above the binding capacity of the plasma. Serum iron values as high as 3,000 µg/dl have been observed. Late coma is the result of hypoxia, metabolic disturbances, and hepatic damage.

P.641

The introduction of deferoxamine as a therapeutic agent has greatly modified the outlook.⁴²⁵ In the setting of acute iron poisoning this hexadentate chelator, which has a high specific affinity for iron, can be given orally and intravenously. The molecular complex is small and is excreted quickly by the kidneys. Nonetheless, it is prudent to manage iron poisoning in consultation with an experienced toxicologist.

Chapter 24

Sideroblastic Anemias

Sylvia S. Bottomley

The sideroblastic anemias are a heterogeneous group of disorders^{1,2} and ³ uniquely characterized by pathologic iron deposits in erythroblast mitochondria^{4,5} (Fig. 24.1A) that are housed within a distinct, mitochondrial ferritin.^{6,7} The iron-glutted mitochondria account for the so-called ring sideroblast, an erythroblast in which numerous Prussian blue-positive granules often appear in a perinuclear distribution, particularly in the later stages of its maturation (Fig. 24.1B).

The basis for the mitochondrial iron accumulation in the various sideroblastic anemias can be regarded as either insufficient generation of heme as a result of primary defects in the heme biosynthetic pathway or from faults in mitochondrial functions that involve iron pathways, creating an imbalance between mitochondrial iron import and its utilization. Iron delivery to the erythroid cell does not appear to be downregulated in the face of these alterations, and iron continues to be transported normally to mitochondria, where it accumulates.^{8,9} Globin synthesis is also reduced, but this effect is secondary, as it can be corrected *in vitro* by the addition of heme.^{10,11}

FIGURE 24.1. Morphologic features of sideroblastic anemia. A: Electron micrograph of an erythroblast with iron-laden mitochondria. B: Bone marrow smear (Prussian blue stain) with ring sideroblasts. C, D: Blood smears (Wright stain) of severe and mild sideroblastic anemia. E: Siderocytes (Wright stain). F: Electron micrograph of a Pappenheimer body in a peripheral red blood cell.

Kinetically, the sideroblastic anemias are characterized by ineffective erythropoiesis, like other erythroid disorders with defective cytoplasmic or nuclear maturation.^{12,13} Erythroid hyperplasia of the bone marrow is accompanied by a normal or only slightly increased reticulocyte count. The plasma iron turnover rate is increased, but

P.644

iron incorporation into circulating red cells is reduced. Red cell survival tends to be normal or slightly reduced. Slight hyperbilirubinemia may be noted, as well as an increase in urobilinogen excretion, as a result of a raised erythropoietic

component of the “early-label” bilirubin peak.¹⁴ Thus, it can be inferred that a substantial proportion of the developing ring sideroblasts are nonviable, and their expiration through enhanced apoptotic mechanisms within the marrow^{15,16,17} accounts for the kinetic abnormalities.

The progeny of surviving ring sideroblasts are often but not always hypochromic and microcytic erythrocytes, a finding that provides morphologic evidence of impaired hemoglobin production as well as an initial clue to the diagnosis. The degree of hypochromia and microcytosis varies considerably from one form of sideroblastic anemia to another (Fig. 24.1C,D). Often, dimorphism is pronounced, with a hypochromic/microcytic population of cells existing side by side with a normal or even a macrocytic one. The siderotic mitochondria of the developing cell may be retained in some circulating erythrocytes (Pappenheimer bodies) and are regularly found with concurrent hypofunction or absence of the spleen; these cells are the nearly pathognomonic siderocytes in the Wright-stained blood smear¹⁸ (Fig. 24.1E,F).

A common feature of many sideroblastic anemias that are not reversible is an excess of total body iron. The serum iron concentration is increased, often to the point of complete saturation of transferrin, and the level of serum ferritin roughly reflects the degree of iron overload. The ineffective erythropoiesis mediates increased intestinal absorption of iron by suppressing hepcidin production.^{19,20} The consequent iron overload state is called erythropoietic hemochromatosis, and its clinical and pathologic features and course can rival those of hereditary hemochromatosis^{21,22} (see Chapter 25). The occasional concomitant presence of alleles for genetic hemochromatosis accentuates the iron overload,^{23,24} and²⁵ but their prevalence in patients with sideroblastic anemia does not appear to be greater than in the general population.^{22,26,27} and²⁸

Diverse defects affecting the utilization of iron by the developing red cell are reflected in the various forms of sideroblastic anemia (Table 24.1). Within the congenital group, the majority appear as isolated anemia, the X-linked and a recently identified autosomal recessive type being the most frequent; however, in a large proportion of cases the cause remains unexplained. Very uncommon are several genetically defined syndromic forms involving multiple systems. Acquired sideroblastic anemia is considerably more common than the congenital forms and occurs as a clonal disorder manifesting only anemia or multilineage dysplasia or even myeloproliferative features. Several diverse factors, such as ethanol, certain drugs, copper deficiency, and hypothermia, produce the ring sideroblast abnormality that is fully reversible.

TABLE 24.1 CLASSIFICATION OF THE SIDEROBLASTIC ANEMIAS (SAs)

Congenital SA

X-linked (XLSA)

Mitochondrial carrier protein SLC25A38 deficiency

Glutaredoxin 5 deficiency

Associated with erythropoietic protoporphyria

Cause unknown

Associated with genetic syndromes

X-linked with ataxia (XLSA/A)

Myopathy, lactic acidosis, and sideroblastic anemia (MLASA)

Congenital sideroblastic anemia and B cell immunodeficiency (SIFD)

Pearson marrow-pancreas syndrome

Thiamine-responsive megaloblastic anemia (TRMA)

Acquired Clonal SA

Refractory anemia with ring sideroblasts (RARS)

Refractory anemia with ring sideroblasts and thrombocytosis (RARS-T)

Refractory cytopenia with multilineage dysplasia and ring sideroblasts (RCMD-RS)

Reversible SA: Associated with

Alcoholism

Certain drugs (isoniazid, chloramphenicol, linezolid)

Copper deficiency (nutritional, malabsorption, zinc ingestion, copper chelation)

Hypothermia

HISTORICAL ASPECTS

The history of sideroblastic anemias can be said to have begun in 1945 with Cooley's report of a family with X-linked microcytic hypochromic anemia²⁹ (Table 24.2). Near that time iron-containing granules in erythroblasts, including their perinuclear distribution, were described separately,^{31,32} and 10 years later were demonstrated to represent iron-laden mitochondria.⁴ Over the next two decades these ring sideroblasts were recognized in pyridoxine-responsive anemia and in numerous patients with "refractory" anemia of unknown cause, hereditary or acquired, forming the basis for a 1965 symposium and adoption of the term sideroblastic anemia.¹ By then, the iron overload of these disorders had also become fully appreciated.^{35,36}

The spectrum of the sideroblastic anemias was widened further by finding various reversible causes of the phenotype as well as by descriptions of certain congenital syndromic forms (Table 24.2). With the advent of molecular biology tools, the genetic causes of several clinically distinct types of congenital sideroblastic anemia and in part their pathogenesis have been elucidated during the last two decades.

HEME SYNTHESIS IN ERYTHROID CELLS

Developing erythroid cells have the greatest requirement of any cell type for heme for hemoglobin, and they produce more than 80% of the heme in the body. The expression and regulation of erythroid heme synthesis are unique in that they are linked (a) to the differentiation events after the signaling action of erythropoietin on erythroid precursors when they acquire the machinery for hemoglobin synthesis, (b) to the availability of iron, and (c) to the production of globin during development of the red cell. As in hepatocytes, 5-aminolevulinic acid (ALA) synthase and porphobilinogen (PBG) deaminase have considerably lower relative activities than the remaining enzymes in the heme biosynthetic pathway (see Chapter 6) and are sites of pathway regulation.⁶² In contrast to the liver, the relative activity of ferrochelatase, the terminal enzyme in the pathway, appears also to be low in erythroid cells.⁶² Furthermore, developing red cells express erythroid-specific isozymes or messenger RNA (mRNA) transcripts of the first four enzymes of heme synthesis, namely ALA synthase, ALA dehydratase, PBG deaminase, and uroporphyrinogen III synthase.

ALA synthase, the first and rate-controlling enzyme of heme synthesis, is generated in the cytosol as a precursor protein with an N-terminal signal sequence that is proteolytically cleaved and processed on transport of the protein into the mitochondrial matrix.^{63,64} The mature mitochondrial protein catalyzes the formation of ALA from glycine and succinyl coenzyme A (CoA) and requires pyridoxal 5'-phosphate (PLP) as an obligate cofactor. Recently it was discovered that the erythroid-specific mitochondrial carrier family protein SLC25A38 importing glycine across the mitochondrial inner membrane to likely meet the high molar requirement of this substrate by the ALAS enzyme is

P.645

necessary for normal erythroid heme synthesis.⁶⁰ Two separate genes encode the ALA synthase isoenzymes.^{65,66} The housekeeping gene (ALAS1), located on chromosome 3,^{66,67} is expressed ubiquitously,⁶⁸ whereas the erythroid-specific gene (ALAS2) is on the X chromosome.^{65,66,69,70} Expression of the housekeeping gene, at least in hepatocytes, is controlled by glucose levels and is increased by certain steroids, various drugs, and chemicals (see Chapter 26). This gene is repressed by administration of heme, the end product of the pathway, so that heme levels tightly regulate transcription of its mRNA in a feedback manner.⁶⁸ Expression of the erythroid gene is essential for hemoglobin production, and ALAS1 cannot compensate if ALAS2 is lacking.⁷¹ ALAS2 is activated and transcribed in concert with other erythroid genes through the action of erythropoietin^{63,68} (Fig. 24.2); it is not repressed by heme but is upregulated by hypoxia.⁷² Cellular iron supply may also control ALAS2 mRNA levels,⁷³ whereas exogenous heme inhibits translation of ALAS2 mRNA,⁷⁴ although the mechanisms by which these occur are not known. Translational regulation of erythroid ALA synthase mRNA is mediated through interaction of its cis-acting iron-responsive element (IRE)^{75,76} with iron regulatory proteins (IRP1 and IRP2; also called IRE binding proteins 1 and 2)^{77,78,79} that are modulated through iron-sulfur (Fe-S) clusters generated in mitochondria and by cellular iron status^{80,81} (Fig. 24.2) (see Chapter 23). In this manner, regulation of protoporphyrin production is linked to iron availability and to mitochondrial function for the formation of heme. The low ALA synthase activity observed in erythroid cells in iron deficiency is consistent with such a control mechanism.⁸² While the signal sequences of the ALAS1 and ALAS2 precursor proteins contain two heme-binding motifs implicated in regulating translocation of the enzyme into mitochondria by interaction of heme with these motifs^{83,84} (Fig. 24.2), mitochondrial import of ALAS2 does not appear to

be affected by heme.⁸⁵ Within the mitochondrion, the ALAS2 isoform uniquely associates with the succinyl-CoA synthetase β A subunit, seemingly to stabilize the ALAS2, to control the generation of its substrate succinyl-CoA, or both.⁸⁶ The role of a major splice isoform of ALAS2 that is functional in vivo⁸⁷ in the regulation of the enzyme or erythroid heme synthesis remains to be determined.

TABLE 24.2 MILESTONES IN THE HISTORY OF SIDEROBLASTIC ANEMIAS

First Description or Discovery	Year	Reference(s)
X-linked microcytic hypochromic anemia by T. Cooley	1945	29
Three brothers with pyridoxine-responsive anemia mentioned	1940s	30
Perinuclear iron-positive granules in erythroblasts	1947	31, 32
Case report of pyridoxine-responsive anemia	1956	33
Acquired refractory anemia with sideroblastic bone marrow	1956	34
Iron deposits in erythroblast mitochondria	1957	4
<i>Sideroblastic anemia</i> term adopted at international symposium	1965	1
Associated iron overload	1965	35, 36
Reversible sideroblastic anemia from antituberculosis agents	1965	37
Experimental sideroblastic anemia with antituberculosis drugs	1965, 1974	38, 39
Reversible sideroblastic anemia from chloramphenicol	1967	40
Reversible sideroblastic anemia from alcohol	1969	41
Thiamine-responsive megaloblastic anemia (Rogers syndrome)	1969	42
Sideroblastic anemia in erythropoietic protoporphyria	1973, 1993	43, 44
Sideroblastic anemia from copper deficiency	1974	45, 46
Pearson marrow-pancreas syndrome	1979	47
Sideroblastic anemia associated with hypothermia	1982	48
X-linked sideroblastic anemia with ataxia (XLSA/A)	1985	49
RARS inclusion in classification of myelodysplastic syndromes	1986	50
Mitochondrial DNA deletion as cause of Pearson syndrome	1989	51
Mutation in <i>ALAS2</i> as cause of XLSA	1992	52
Mutation in <i>ABCB7</i> as cause of XLSA/A	1999	53
Mutations in <i>SLC19A2</i> as cause of TRMA	1999	54,55 and 56
MLASA and causative mutation in <i>PUS1</i>	2004	57,58
Mutation in <i>GLRX5</i> as a cause of AR sideroblastic anemia	2007	59
Mutations in <i>SLC25A38</i> as cause of AR sideroblastic anemia	2009	60
Mutation in <i>YARS2</i> as another cause of MLASA	2010	61

AR, autosomal recessive; MLASA, myopathy, lactic acidosis, and sideroblastic anemia; RARS, refractory anemia with ring sideroblasts; TRMA, thiamine-responsive megaloblastic anemia; XLSA, X-linked sideroblastic anemia; XLSA/A,

X-linked sideroblastic anemia with ataxia.

ALA dehydratase, a cytosolic enzyme, catalyzes the formation of the pyrrole PBG from two molecules of ALA. For this enzyme, two tissue-specific isozymes are produced by a single gene, which contains two promoter regions, generating housekeeping and erythroid-specific transcripts with alternative first noncoding exons (exons 1A and 1B).^{88,89} Although both transcripts encode identical polypeptides, the erythroid-regulated form would provide for the production of the large amounts of heme for hemoglobin. Not being a rate-limiting enzyme for heme biosynthesis, its expression in erythroid cells in manyfold excess amounts⁶² may also serve as the proteasome inhibitor CF-2 to inhibit protein degradations.⁹⁰

P.646

FIGURE 24.2. Pathways of regulation of erythroid 5-aminolevulinic acid synthase (ALAS2). Epo, erythropoietin; Fe-S, iron-sulfur cluster; Tf, transferrin; TfR, transferrin receptor; IRE-BP, iron-responsive element binding protein; - denotes inhibition, + denotes stimulation. (Modified from May BK, Dogra SC, Sadlon TJ, et al. Molecular regulation of heme biosynthesis in higher vertebrates. *Progr Nucleic Acid Res Mol Biol* 1995;51:1-51.)

In the case of PBG deaminase, which acts in the cytosol to form the linear tetrapyrrole hydroxymethylbilane from four molecules of PBG (see Chapter 6), two tissue-specific isoenzymes also are produced by a single gene.⁹¹ The gene has two

overlapping transcription units, each with its own promoter: an upstream ubiquitous promoter and another downstream promoter active only in erythroid cells. Two mRNAs are generated by alternative splicing, one encoding the ubiquitous PBG deaminase isoenzyme and the other encoding the erythroid isoenzyme. To what extent the erythroid-specific enzyme has a regulatory role in the overall production of heme in erythroid cells is not known. In response to erythropoietin or hypoxia, bone marrow PBG deaminase activity increased 3.5-fold, apparently by de novo synthesis.⁹²

The gene for uroporphyrinogen III synthase likewise has two promoters generating housekeeping and erythroid-specific transcripts with unique 5'-untranslated sequences (exons 1 and 2A).⁹³ As for ALA dehydratase and PBG deaminase, the erythroid promoter activity is increased during erythroid differentiation. Uroporphyrinogen decarboxylase, the fifth enzyme of the pathway with its site of action in the cytosol, is not known to have erythroid-regulatory features; however, its mRNA is markedly increased in erythroid tissue⁹⁴ and the enzyme activity is higher in erythroid cells than in the liver.⁶²

After translation, all three terminal enzymes of heme biosynthesis (coproporphyrinogen oxidase, protoporphyrinogen oxidase, ferrochelatase), like ALA synthase, are transported to their mitochondrial sites of action. Single genes encode these enzymes, and erythroid-specific transcription products are not known for them. However, erythroid-specific regulation of their expression is accommodated by the presence of promoter sequences in their genes for binding of erythroid transcription factors (e.g., GATA-1, NFE-2)^{95,96} and⁹⁷ to enhance production of these enzymes during erythropoiesis.⁹⁸ Ferrochelatase, the last enzyme of the heme synthetic pathway, catalyzes the insertion of iron into protoporphyrin to form heme. A repressor sequence in the promoter region of its gene is believed to be involved in the regulation of the binding of the erythroid transcription factors GATA-1 and NFE-2 to their recognition sites.⁹⁷ The activity of ferrochelatase relative to the activity of ALA synthase is in considerable excess,^{62,99} but the enzyme becomes rate-limiting as a defective protein in erythropoietic protoporphyria (see Chapter 26). As it contains an Fe-S cluster, its expression and stability are also dependent on cellular iron levels and intact Fe-S cluster assembly machinery,^{100,101} and its activity is regulated by the essential mitochondrial ATPase inhibitory factor 1 (Atpif1) through modulation of mitochondrial pH and redox potential.¹⁰²

P.647

The large amounts of iron required for erythroid heme synthesis are delivered through transferrin receptor-mediated endocytosis of iron transferrin (see Chapter 23), and iron availability ultimately limits the normal rate of heme synthesis in erythroid cells.¹⁰³ High expression of transferrin receptors is also linked to erythropoietin-induced differentiation^{68,103}; an erythroid-specific isoform of human transferrin receptor has been described¹⁰⁴; and erythroid-active elements have been identified in the promoter of the murine gene.^{105,106} During the height of hemoglobinization, the erythroid cell may not depend upon the "standard" mode for regulation of intracellular iron homeostasis via the IRE/IRP system to ensure a maximal supply of iron to mitochondria.¹⁰⁷ With erythroid maturation and the accumulation of cellular hemoglobin, the transferrin receptor number progressively decreases.¹⁰³ While surface transferrin receptors and iron uptake are increased in iron-deficient erythroblasts,^{108,109} they are not altered in states of impaired heme synthesis, such as in the presence of succinylacetone¹¹⁰ or in erythroid cells from patients with sideroblastic anemia.⁸ Transport of iron out of the endosome by the divalent metal transporter DMT1 requires an endosomal ferrireductase (Steap3) in erythroid cells.¹¹¹ How the further transfer of iron to mitochondria and to apoferritin is accomplished is not understood. It may be facilitated by a cytoplasmic chaperone,¹¹² or through direct interaction of endosomes with mitochondria.¹¹³ Iron is imported across the mitochondrial inner membrane by mitoferrin 1 that is highly expressed in erythroid cells and stabilized by interacting with the ATP-binding cassette protein ABCB10.^{114,115} An oligomeric complex of mitoferrin 1, ABCB10 and ferrochelatase appears to facilitate the incorporation of iron into protoporphyrin to form heme.¹¹⁶ Iron imported into the mitochondrion is also used for the generation of Fe-S clusters, which in part are exported to the cytosol for their addition to IRP1 in the regulation of cellular iron uptake⁸¹ and translation of ALAS2,¹¹⁷ and for expression of ferrochelatase.^{100,101}

TABLE 24.3 GENETIC AND HEMATOLOGIC FEATURES OF THE CONGENITAL SIDEROBLASTIC ANEMIAS (CSAs)

Mode of Inheritance	Defective Enzyme/Protein	Gene/Chromosomal Location of Gene	Erythrocyte		Severity of Anemia
			Mean Corpuscular Volume	Protoporphyrin	

X-linked sideroblastic anemia	X-linked ALAS2	ALAS2/Xp11.21	Decreased ^a	Decreased	Mild to severe	
Mitochondrial carrier protein deficiency	Autosomal	SLC25A38	SLC25A38/3p22.1	Decreased	Decreased	Severe
Glutaredoxin 5 deficiency	Autosomal	Glutaredoxin 5	GLRX5/14q32.13	Decreased	Not reported	Mild to severe
Protoporphyrinemia	Autosomal	Ferrochelatase	FECH/18q21.3	Decreased	Markedly increased	Mild
Unknown cause	?	?	Variable	Variable	Mild to severe	
X-linked sideroblastic anemia with ataxia	X-linked	ABCB7 mitochondrial transporter	ABCB7/Xq13.1-q13.3	Decreased	Increased	Mild
Myopathy, lactic acidosis, and sideroblastic anemia	Autosomal	Pseudouridine synthase 1	PUS1/12q24.33	Normal/increased	Not reported	Severe in time
		Mitochondrial tyrosyl tRNA synthetase	YARS2/12p11.21	Not reported	Not reported	Severe
CSA and B cell immunodeficiency	Autosomal	?	?	Decreased	Not reported	Severe
Pearson syndrome	Sporadic/maternal	Respiratory chain components	Multiple/mitochondrial DNA	Increased	Increased	Severe
Thiamine-responsive megaloblastic anemia	Autosomal	Thiamine transporter	SLC19A2/1q23.3	Increased	Normal/increased	Mild to severe

^a Often normal or increased in females expressing the disorder.

The export of heme out of the mitochondrion into the cytosol for its pairing with globins of hemoglobin and other heme proteins is mediated at least in the mouse by an isoform of the feline leukemia virus C receptor (FLVCR1), named FLVCR1b¹¹⁸. This heme exporter is essential for erythropoiesis as its loss leads to heme accumulation in the mitochondrion and termination of erythroid differentiation.

The events coordinating the production of globin chains with the rate of heme synthesis are well understood, and appear to occur at more than one level. Heme is required for initiation of globin mRNA translation and it acts by inhibiting a protein kinase called heme-regulated inhibitor (HRI), which inactivates the translational initiation factor 2 (eIF-2 α) in the absence of heme¹¹⁹ (Fig. 24.2). Moreover, absence of this kinase adversely modifies the phenotype of disorders of heme synthesis (iron deficiency, protoporphyria) and of globin production (β -thalassemia).¹¹⁹ In addition, heme controls globin gene expression at the transcriptional level.^{120,121}

CONGENITAL SIDEROBLASTIC ANEMIAS

Congenital sideroblastic anemias have emerged as not uncommon disorders. They are clinically and genetically heterogeneous, with diverse underlying causes, inheritance patterns, phenotypes, and associated features. Genetic analysis and molecular approaches have revealed a spectrum of specific defects, some appearing as isolated anemia and others involving multiple systems^{3,122,123} (Table 24.3). Defined underlying defects affect heme biosynthesis directly or indirectly by disrupting Fe-S cluster biogenesis, or they involve pathways related to mitochondrial protein synthesis. However, in at least one third of cases the root cause remains undiscovered. Severity of anemia is highly variable within some types, and morphologic features overlap among them.

P.648

Genetic Defects Expressed Only in the Erythron

Inheritance Patterns and Pathogenesis

X-Linked Sideroblastic Anemia

The inheritance follows an X-linked pattern, the anemia occurring most commonly in males and their maternal uncles and cousins.^{29,124,125,126,127} and ^{128,129,130} Minimal expression of the erythroid abnormality may be seen in carrier females that is consistent with variable X inactivation affecting the mutant locus of the disorder. However, in many kindreds, the anemia has occurred only in females and may have been lethal in hemizygous male conceptions.^{131,132,133,134,135,136}

Early observations already implicated defects in ALA synthase as underlying the impaired heme biosynthesis in this form of sideroblastic anemia. In patients who responded to pyridoxine supplementation, the incorporation of glycine, but not of ALA, into heme was reduced in reticulocytes.³⁰ ALA synthase activity in bone marrow was low before pyridoxine administration and returned to normal or supranormal levels after an erythropoietic response.^{129,137,138} and ¹³⁹ It was presumed that the residual activity or stability of a defective erythroid ALA synthase was enhanced by additional supply of its coenzyme PLP through a mass action effect (e.g., if the enzyme had a reduced affinity for the coenzyme¹³⁸ or was abnormally sensitive to proteolysis¹³⁷). Usually, pharmacologic amounts of pyridoxine are required when an erythropoietic response occurs, but the response is variable and rarely complete. Individuals may present with profound anemia only in adulthood or even late in life,^{129,140,141,142} suggesting that the disorder can progress with time. In some cases, prior additional dietary or medicinal intake of pyridoxine,¹⁴³ possible changes in pyridoxine metabolism with advancing age,¹⁴⁴ or initiation of hemodialysis^{145,146} can be factors in unmasking mild phenotypes that were not symptomatic at a younger age. In female patients expressing the disease, skewed X inactivation in hematopoietic tissue that occurs with advancing age¹⁴⁷ and involves progressive inactivation of the X chromosome bearing the normal allele has been the explanation as the anemia usually evolved in adulthood^{135,136} or late in life.¹⁴⁸ Constitutive skewed X inactivation to account for disease expression in females in childhood is very uncommon.¹³⁶

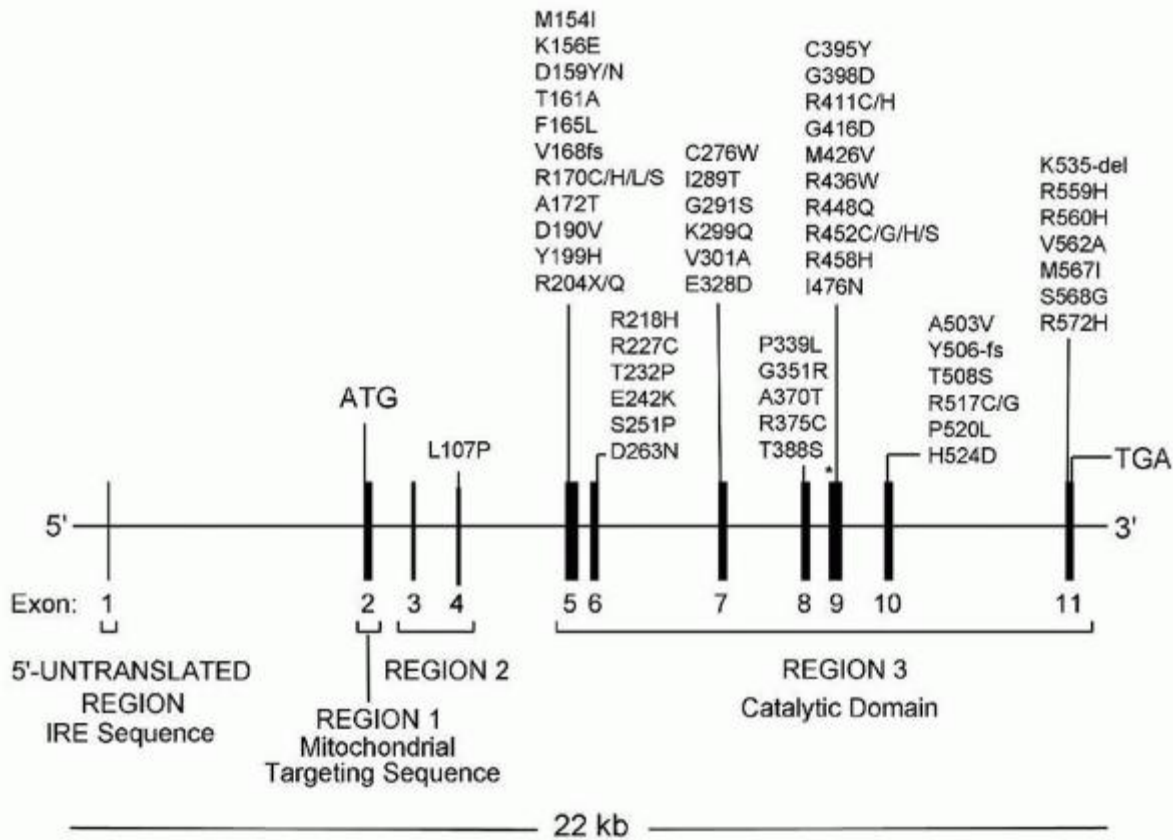

FIGURE 24.3. Diagram of the structure of the human erythroid 5-aminolevulinic acid synthase gene (ALAS2) and the location of mutations identified to date in X-linked sideroblastic anemia. Two mutations in the promoter region (c.-206C>G; c.-91_44del) and two mutations disrupting the intron 1 enhancer of ALAS2 are not indicated. IRE, iron-responsive element; kb, kilobases. *Codon K391, the pyridoxal 5'-phosphate binding lysine. (Data from HGMD® Professional 2012.2 and unpublished material.)

After the cloning and characterization of the erythroid ALA synthase gene^{75,149} and its localization to the X chromosome, linkage of the disorder to the ALAS2 locus was established,^{129,150} and many heterogeneous missense mutations involving invariant or highly conserved amino acid residues in the catalytic domain of the enzyme have been found to cause the disorder¹⁵¹ (Fig. 24.3). A nonsense mutation in one case,¹³⁵ nucleotide deletions, and regulatory mutations in the promoter region and in the intron 1 enhancer sequence^{151a} of the ALAS2 gene have been the exceptions. Hence, in at least four families described up to 68 years ago,^{29,125,128,152} the underlying molecular defect in ALAS2 could also be defined.^{25,153,154} and ¹⁵⁵ A majority of the mutations identified to date reside in exons 5 and 9 (Fig. 24.3); the latter contains the PLP-binding lysine (K391) of the enzyme.¹⁵⁶ Among the 66 distinct mutations so far encountered, only 22% occurred in more than one unrelated family or proband, and nearly one third of the probands are female. An apparent somatic mutation in the ALAS2 gene was found in an older male patient with acquired sideroblastic anemia.¹⁵⁷

Sites of ALAS2 mutations and severity of anemia or extent of its responsiveness to pyridoxine supplements can be correlated to a considerable extent. The activity of the recombinant enzyme is reduced for many, but not all, ALAS2 mutants so far examined and is variably enhanced by PLP.^{52,129,130,142,153,158,159} Some mutants have altered substrate kinetics^{159,160} or fail to bind to the β -subunit of succinyl-CoA synthetase.^{86,160} A three-dimensional structure model of the human enzyme¹⁶¹ and the resolved crystal structure of the significantly homologous ALAS of *Rhodobacter capsulatus*¹⁶² made it possible to explain how altered structure by many of the naturally occurring mutations that give rise to X-linked sideroblastic anemia (XLSA) affects the function of the enzyme. For example, mutations changing an amino acid located in the vicinity of the PLP-binding site exhibit a response to pyridoxine, whereas mutations involving sites of substrate binding, enzyme stability, or folding are refractory to pyridoxine.¹⁶² However, while clinical severity can thus be related at least in part to the effect of a specific mutation on enzyme function, marked variation in severity of anemia has been observed between some kindreds bearing the same mutation as well as within a few

kinships,^{129,130,163,164} implicating undefined genetic differences or environmental factors for the apparent variable penetrance.

Mitochondrial Carrier Protein SLC25A38 Deficiency

A significant segment of congenital sideroblastic anemias (~15%) is associated with biallelic mutations in the gene encoding the erythroid-specific mitochondrial inner membrane carrier protein SLC25A38.^{60,165} The SLC25A38 gene has an amino terminal targeting signal and three mitochondrial carrier family protein domains that encode six transmembrane helices. From its structural features, the protein is predicated to function as an amino acid transporter. Data so far obtained in the yeast *Saccharomyces cerevisiae* deficient in the protein indicate a heme biosynthetic defect and suggest that it serves as a glycine importer across the mitochondrial inner membrane.⁶⁰

Heterogeneous mutations spread throughout the SLC25A38 protein domains have been reported in 26 families, including three sibling pairs.^{60,166} The mutations are missense type occurring in conserved amino acids at substrate contact points as well as nonsense and splicing errors. Two thirds of patients are homozygous and one third are compound heterozygotes for defects.

Glutaredoxin 5 Deficiency

The human counterpart of a zebrafish mutant (shiraz) deficient in glutaredoxin 5,⁸⁰ which is essential for the synthesis of Fe-S clusters such as for IRP1 and thus ALAS2 translation, was identified in a single patient.⁵⁹ A homozygous mutation in the GLRX5 gene that affects intron 1 splicing and markedly reduces GLRX5 RNA production was associated with microcytic sideroblastic anemia. The anemia was detected in the fifth decade, became severe by age 60, and improved with iron chelation therapy for the associated iron overload. Studies in cell lines derived from the patient indicated severe impairment of Fe-S cluster biogenesis and also revealed markedly reduced levels of ferrochelatase.¹⁶⁷

Sideroblastic Anemia in Protoporphyrin

Marked deficiency of ferrochelatase underlies erythropoietic protoporphyria as a result of a large variety of mutations in the gene encoding the enzyme (see Chapter 26). The defect is manifested mainly, if not exclusively, in erythroid cells and leads to marked accumulation of free protoporphyrin, the substrate of the enzyme, during the final stages of erythroid maturation when the defective ferrochelatase becomes rate-limiting for heme production.¹⁶⁸ Erythroid heme synthesis appears to be compromised in most patients as reflected in a mild microcytic hypochromic anemia.¹⁶⁹ In ten patients marrow ring sideroblasts with typical mitochondrial iron deposits were observed^{43,44} but not in one sibling pair with mild microcytosis without anemia.¹⁶⁸ Bone marrow examination has generally not been performed in this disorder so that the incidence of the ring sideroblast feature is not known. The genetic heterogeneity in protoporphyria may account for the phenotypic variation of hematologic features.

Undefined Congenital Sideroblastic Anemia(s)

It is estimated that at least one third of nonsyndromic cases of congenital sideroblastic anemia are currently molecularly unexplained.¹⁶⁵ These may have autosomal or X-linked defects not yet detectable in the known causative genes, or defects in novel genes to be discovered. Novel genetic defects are also likely in some previously described kindreds. For example, in two families sideroblastic anemia occurred in a vertical distribution including father-to-son transmission and consistent with a dominant trait.^{170,171} In another family manifesting the anemia in both genders, a defect in mitochondrial DNA was postulated¹⁷²; the mild anemia was characterized by erythrocyte dimorphism and macrocytosis.

Clinical and Laboratory Features of XLSA and SLC25A38 Deficiency

If severe, XLSA is recognized in infancy or early childhood. However, not infrequently the disorder is milder or asymptomatic and may be discovered only in young adulthood or even in later life. Because severity of anemia can also vary within kindreds,^{129,130,164} diagnosis in family members may be delayed or overlooked unless complete pedigree studies or DNA analyses for an ALAS2 mutation identified in the proband are performed. In contrast, patients with SLC25A38 genetic defects typically present at birth or in early childhood with severe anemia.

All patients develop manifestations of iron overload. Linkage to human leukocyte antigen (HLA) is not evident²² as HFE mutations were underrepresented in a series of XLSA patients examined.²⁶ Mild to moderate enlargement of the liver and spleen is common, but liver function usually is normal or only mildly disturbed at presentation. Liver biopsy reveals iron deposition that is indistinguishable from hereditary hemochromatosis³⁶ (Fig. 24.4). In the X-linked form the iron burden does not correlate with the severity of anemia, and, not infrequently, well-established but asymptomatic micronodular cirrhosis is discovered in the third or fourth decade.^{22,36,134,141,173} Hepatocellular carcinoma developed in two reported

cases.^{163,174} Clinical diabetes or abnormal glucose tolerance may or may not be related to the iron overload process. Skin hyperpigmentation is uncommon. The most dangerous manifestations of the iron overload are cardiac arrhythmias and congestive heart failure, which usually occur late in the disease course. In severely affected infants or young children, growth and development tend to be impaired.¹²⁷

The hallmark is a microcytic anemia. In severe cases, microcytosis and hypochromia are pronounced (mean corpuscular volume [MCV], 50 to 60 fl), and striking anisocytosis, poikilocytosis, target cells, and occasional siderocytes are prominent findings on blood smear (Fig. 24.1C). The red cell volume distribution is usually abnormally wide and, notably, dimorphism is seen in males with the X-linked form¹²⁴ as well as in autosomal forms of the disease.^{60,166,170} Some female carriers of the X-linked trait have a biphasic Coulter counter red cell histogram^{25,128} (Fig. 24.5), or only a very small microcytic erythrocyte population. However, most women who express XLSA exhibit macrocytosis, although dimorphism may be evident (Fig. 24.1D). Presumably few viable erythrocytes with a markedly defective or nonfunctional mutant ALAS2 enzyme as often encountered in women reach the circulation, so that most of the erythrocytes are progeny of the residual normal clone that are released from the marrow at an accelerated rate in response to the anemic hypoxia. Leukocyte and platelet values usually are normal; they may be reduced in the presence of splenomegaly (hypersplenism). Erythroid hyperplasia is found on marrow examination, and maturation is usually normoblastic with poorly developed cytoplasm. Megaloblastic changes may be observed if complicating folate deficiency is present. Marrow reticuloendothelial iron is increased, and the telltale ring sideroblast emblem is prominent in late, nondividing erythroblasts.^{175,176} Transferrin saturation is increased, as is the serum ferritin level, and transferrin levels tend to be decreased. Ferrokinetic studies reflect ineffective erythropoiesis. A reduced serum haptoglobin level is consistent with the ineffective erythropoiesis.

The erythrocyte protoporphyrin level usually is low or normal.^{12,131} In one female patient, the low protoporphyrin level was shown to be restricted to the microcytic red cells.¹³² Kindreds in which the erythrocyte protoporphyrin is increased^{131,170} can be considered to represent disorders other than XLSA or SLC25A38 deficiency.

Treatment and Prognosis

Approximately two thirds of patients with sideroblastic anemia due to identified ALAS2 defects can be expected to respond to

P.650

pyridoxine administration. Doses of 50 to 100 mg/day are large compared with the estimated adult daily requirement for vitamin B₆ of 1.5 to 2.0 mg and are sufficient for a maximal response, although in some cases a supplement of only 2 to 4 mg/day was found to be effective.¹²⁹ Higher doses may be toxic. No convincing evidence is available that the parenteral route or PLP, the active coenzyme form, is more effective than oral administration. However, the response to pyridoxine is quite variable. With an optimal response, reticulocytosis is observed, blood hemoglobin concentration returns to normal or near-normal levels in 1 to 2 months, and low erythrocyte protoporphyrin levels increase to normal.^{12,177} The morphologic red cell abnormalities then

P.651

diminish but very rarely completely resolve, even when ALA synthase activity and the hemoglobin level are restored with pyridoxine supplementation. Approximately two thirds of responding patients experience a distinct but suboptimal improvement with pyridoxine administration, and the hemoglobin concentration stabilizes at less than normal levels. When an effect of pyridoxine is achieved, continued maintenance treatment is necessary because relapses follow within several months after discontinuance of the vitamin. In a few instances, subsequent remissions with resumed treatment were less complete.¹² In the occasional case with accompanying megaloblastic changes, folic acid should be given, which usually leads to normoblastic maturation, suboptimal reticulocytosis, and some increase in the hemoglobin level. In severely anemic individuals who do not respond to pyridoxine, periodic red cell transfusions are necessary to relieve symptoms and to allow normal growth and development of children. Transfusion of red cells should be kept to a minimum to lessen or delay the development of iron overload.

FIGURE 24.4. Histopathology of the iron overload in congenital sideroblastic anemia. A, B: Liver section of a 26-year-old man with SLC25A38 deficiency and moderate hemochromatosis. C, D: Autopsy liver section of a 45-year-old man with X-linked sideroblastic anemia, micronodular cirrhosis, and hemochromatosis. E, F: Section from the heart of the latter patient with marked hemosiderosis. (A, C, and E: Hematoxylin stain; B, D, and F: Prussian blue stain.)

FIGURE 24.5. Dimorphic red cell distribution in a female patient with mild X-linked sideroblastic anemia. Redrawn from the output of a Coulter analyzer. RBC, red blood cell.

Based on the assessed extent of iron overload, including liver biopsy, an iron depletion program should be instituted to prevent or stabilize already established organ damage.^{134,178,179,180} Therapeutic phlebotomies are well tolerated and preferred in patients with mild or moderate anemia in the absence of contraindications such as heart disease.^{134,173,181,182} and¹⁸³ After the initial removal of all storage iron, maintenance phlebotomies should be continued indefinitely. For patients with severe anemia, or for those who depend on regular transfusions and thus become massively iron loaded,^{184,185} an iron-chelating agent is administered. As recommended for thalassemia,¹⁸⁵ deferoxamine is infused over 12 hours subcutaneously or intravenously, at 40 mg/kg/day, and for at least 5 days each week. Although iron removal with deferoxamine is enhanced by ascorbate, large supplements can cause acute cardiac toxicity by facilitating excessive mobilization of ferritin iron, and any intake of the vitamin should be limited to 200 mg daily.¹⁸⁶ The risks of deferoxamine treatment are minimal.^{179,187} Occasional local reactions can be controlled with inclusion of small amounts of hydrocortisone in the infusate. Rare hypersensitivity is amenable to desensitization.¹⁸⁸ Reported visual and auditory neurotoxicity is unlikely without excessive doses of the drug. The new, orally active tridentate iron chelator deferasirox (Exjade) has an efficacy similar to deferoxamine or better^{180,189}; the recommended initial daily dose is 20 mg/kg and can be increased to 30 mg/kg. Although the long-term safety profile of this agent is not known, it has emerged as a preferred iron chelator. The goal of iron chelation therapy is to maintain the serum ferritin concentration below 500 µg/L. The increased risk of infection with *Yersinia* (and perhaps other organisms) in iron overload, although uncommon, increases further with deferoxamine treatment.^{179,190} Removal of the iron excess has occasionally reduced severity of the anemia^{8,25,182,183} by improving erythroblast mitochondrial function, such as restoration of secondary ferrochelatase deficiency¹⁸³; by enhancing pyridoxine responsiveness²⁵; and by diminishing the ineffective erythropoiesis.¹⁸²

Splenectomy in congenital sideroblastic anemia appears to be invariably complicated by thromboembolic complications and, often, a fatal outcome.^{140,141,153,191,192} Factors other than persistent thrombocytosis seem to play a role. Control of the platelet count and anticoagulant therapy usually are not effective, so splenectomy is contraindicated.

These supportive measures provide for a favorable prognosis and often for normal survival. Curative bone marrow transplantation was achieved in seven reported patients without known molecular defects,^{193,194,195,196} and¹⁹⁷ including recovery from chronic graft-versus-host disease after subsequent orthotopic liver transplantation in one of these cases¹⁹⁸; one patient succumbed to graft-versus-host disease and prior iron overload.¹⁹⁶ Hematopoietic stem cell transplantation has also been successful in several unreported cases with SLC25A38 deficiency.

In contrast to acquired clonal sideroblastic anemia, predisposition to leukemic evolution has not been observed.

Sideroblastic Anemia as a Component of Genetic Syndromes

X-Linked Sideroblastic Anemia with Ataxia

In a large kindred with XLSA associated with nonprogressive ataxia (XLSA/A),⁴⁹ linkage to the phosphoglycerate kinase locus at Xq13 was demonstrated¹⁹⁹ and linkage to ALAS2 was excluded using a highly polymorphic repeat sequence within intron 7 of the ALAS2 gene.⁷⁰ Cloning and chromosomal mapping to Xq13.1-q13.3 of the human ABCB7 gene,^{200,201} an ortholog of the ATM1 gene in yeast that encodes a transporter protein required for mitochondrial iron homeostasis,²⁰² led to identification of a mutation in this gene as the underlying defect in the kindred.⁵³ Distinct mutations in the ABCB7 gene have been identified in three additional families.^{203,204,205} All the mutations result in substitutions of conserved amino acids (Ile400Met, Glu433Lys, Val411Leu, Glu209Asp) and affect a region of the protein involved in binding and transport of a substrate. It is postulated that ABCB7 participates in the export of Fe-S clusters generated in mitochondria for assembly of cytosolic Fe-S cluster-containing proteins.²⁰⁶ Expression of wild-type ABCB7, but not mutant ABCB7, in Atm1p-deficient yeast restores phenotypic defects as well as the production of cytosolic Fe-S proteins.²⁰³ As in yeast,²⁰⁶ a defective ABCB7 protein leads to mitochondrial siderosis in the human disorder. How heme synthesis becomes impaired in erythroid cells has not been elucidated and may be a consequence of reduced Fe-S cluster biogenesis impacting on the translation of ALAS2.^{80,167} Because free protoporphyrin, as well as zinc protoporphyrin, accumulates in erythrocytes,^{49,203,204,205} the generation of ferrochelatase,^{101,207} an Fe-S-containing protein, is probably affected. Neither ALA synthase nor ferrochelatase has been examined in erythroid cells with the XLSA/A defects. The mechanism for the neural dysfunction in this disorder remains elusive. As in Friedreich ataxia,²⁰⁸ disrupted mitochondrial iron homeostasis in neural cells is likely involved in the pathogenesis.

Among five kindreds so far encountered, the neurologic features are overriding and include delayed motor and cognitive development, incoordination, and nonprogressive cerebellar atrophy with or without atrophy of pons and medulla.^{49,203,204,205,209} The anemia is mild to moderate, and morphologic features are indistinguishable from the isolated heritable forms of sideroblastic anemia, including variable abnormalities in female carriers as observed in XLSA. Both free and zinc-chelated erythrocyte protoporphyrin are increased. Iron overload has not been evident.

P.652

Mitochondrial Myopathy, Lactic Acidosis, and Sideroblastic Anemia

This autosomal recessive disorder results from mutations in the genes encoding either pseudouridine synthase (PUS1)^{58,165,210,211} or mitochondrial tyrosyl transferase (YARS2).^{61,212} In the former, missense or nonsense mutations so far described predict an inactive protein. Mitochondrial and cytoplasmic transfer RNAs lack pseudouridine at the expected sites,²¹³ likely causing faulty translation of mitochondrial genes of respiratory complexes I and IV. The YARS2 mutations reduce levels of the enzyme and lead to decreased mitochondrial protein synthesis and respiratory chain dysfunction.⁶¹ How these protein deficiencies lead to mitochondrial iron accumulation and anemia is unclear.

The PUS1 defects have occurred in four families of Jewish Iranian descent, in one family from the Shetland Islands, and in one Italian family^{57,58,165,210,211}; in the Iranian families consanguinity was present, and parents of the Italian brothers were distantly related. The disorder is characterized by muscle weakness, basal lactic acidemia and normocytic sideroblastic anemia with clinical onset in childhood or around adolescence.⁵⁷ Some cases have exhibited intellectual impairment and/or craniofacial abnormalities. Diminished oxidative phosphorylation is reflected in decreased activity of mitochondrial enzymes of the respiratory chain as well as in the raised blood lactic acid level. The myopathy and the anemia are variably progressive, and transfusions are usually required by the third decade of life if not earlier.

Based on reports of one family and two further unrelated cases with YARS2 mutations,^{61,212} the myopathy and anemia appear of variable severity. While some cases developed a cardiomyopathy, intellectual impairment or developmental abnormalities were not observed.

Congenital Sideroblastic Anemia and B-Cell Immunodeficiency

A novel syndrome of severe microcytic sideroblastic anemia that is associated with B-cell immunodeficiency, periodic fevers and developmental delay and presents in infancy has been described in 12 children.^{213a} In addition, neurologic defects and other multisystem derangements are variably present. Commonly early death was attributed to cardiac or multi-organ failure. The molecular etiology remains to be determined.

Pearson Marrow-Pancreas Syndrome

This progressive, congenital multisystem mitochondrial disorder is associated with sporadic major deletions, rearrangements, or duplications of mitochondrial DNA, leading to the loss of multiple proteins encoded by the mitochondrial genome.^{214,215} About one half of cases are heteroplasmic for a 4,977 bp deletion that involves mitochondrially encoded subunits of respiratory complex I (NADH dehydrogenase), complex IV (cytochrome c oxidase), and complex V (ATP synthase) as well as several mitochondrial tRNA genes.²¹⁵ Thus, translation of mitochondrial DNA-encoded proteins may be affected. The spectrum of mitochondrial genomic deletions has also extended to other non-overlapping deletions. The heteroplasmic nature of mitochondrial DNA at the cellular and organ levels is considered to account for the high variability of tissues involved over time.

The disorder generally presents within the first 6 months after birth with anemia, metabolic acidosis, and exocrine pancreatic insufficiency. Also common is development of hepatic and renal failure. Some infants lack the metabolic derangements initially and present only with anemia, resulting in oversight of this syndrome. Usually 25% are anemic in the neonatal period; by 6 months of age, anemia is evident in 75% of cases. Any associated neutropenia and thrombocytopenia are mild. The anemia tends to be severe and is normocytic or macrocytic.²¹⁶ In the bone marrow, erythroid precursors are often reduced in number but ring sideroblasts are prominent, in which abnormalities in mitochondrial ultrastructure are pronounced.²¹⁷ A distinctive feature is the presence of striking vacuoles in myeloid and erythroid precursors.⁴⁷ Erythrocyte protoporphyrin values were increased when measured.

Approximately one half of patients succumb to the metabolic derangements. The anemia may improve or remit in up to one third of cases by 10 years of age. Survivors often develop the Kearns-Sayre syndrome.^{214,218}

Thiamine-responsive Megaloblastic Anemia

This autosomal recessive syndrome, also known as Rogers syndrome,⁴² is caused by mutations in the SLC19A2 gene, which encodes a 497 amino acid high-affinity thiamine transporter.^{54,55,56} The protein is predicted to have 12 transmembrane spanning regions. Twenty-eight distinct mutations have been reported to date.²¹⁹ Most of these are nonsense or frameshift type; missense mutations result in proteins that are not properly targeted to the cell membrane for their site of function.^{220,221} The dominating megaloblastic feature of the anemia is considered to be due to defective nucleic acid synthesis because limited intracellular thiamine impairs the pentose phosphate pathway and de novo synthesis of ribose-5-P.²²² The unique additional feature of marrow ring sideroblasts may relate to the role of thiamine in the generation of succinyl-CoA, a substrate of ALAS2.²²³

The cardinal clinical characteristic of the syndrome is the triad of megaloblastic anemia, non-type I diabetes mellitus, and sensorineural deafness. Other clinical features have been described in some cases.²¹⁹ The disorder has typically manifested between infancy and adolescence.^{219,224} Some patients have a milder phenotype, and a few have presented as adults.

Hematologic findings are macrocytic anemia, variable degrees of neutropenia and thrombocytopenia with megaloblastic changes and fewer marrow ring sideroblasts than in other congenital sideroblastic anemias.²²⁴ Thiamine (vitamin B1) in pharmacologic doses (25 mg/day) usually improves the anemia and the diabetes initially, but it has become ineffective in adulthood.²²⁵

Animal Models of Sideroblastic Anemia

The first genetically designed animal model of sideroblastic anemia was developed in zebrafish (the sau mutant, sauternes), in which hematopoiesis resembles that of higher vertebrates also at the molecular level, as hematopoietic gene expression and function are conserved.²²⁶ The chemically induced mutant gene encodes the zebrafish ortholog of human ALAS2 and expresses embryonic hypochromic anemia with severe heme deficiency. The two mutation sites, predicting Val249Asp and Leu305Gln substitutions, are in exon 6 and exon 7, respectively, and represent conserved amino acids across large phylogenetic boundaries, including the human. However, the mutants' blood cells did not reveal ring sideroblasts, perhaps because of species differences in cellular iron metabolism.

A second model in zebrafish (the sir mutant, shiraz) has a deficiency of glutaredoxin 5, an essential component of Fe-S cluster assembly, and expresses hypochromic anemia.⁸⁰ In the absence of the Fe-S cluster, the iron regulatory protein IRP1 blocks ALAS2 translation by binding to the IRE of the ALAS2 mRNA. As in the ALAS2 zebrafish mutant, ring sideroblasts were not observed and may reflect species differences.

In a transgenic mouse model with homozygous deficiency of ALAS2, erythroid differentiation is arrested, and embryos die by day 11.5.⁷¹ Mice chimeric for ALAS2-null mutant cells or transgenic mice generated with partial ALAS2 expression²²⁷ exhibit the phenotype of human XLSA, with severe anemia and typical ring sideroblasts in the marrow.

In another mouse model, deletion of the *Abcb7* gene led to fatal neonatal bone marrow failure, demonstrating that *Abcb7* is

P.653

essential for hematopoiesis.²²⁸ While marrow ring sideroblasts were not observed in these animals or in animals chimeric for the human *Abcb7* mutation Glu433Lys, siderocytes were detected in the peripheral blood.

The combination of isoniazid (INH) and cycloserine administered to guinea pigs produces sideroblastic anemia in a few weeks.^{38,39} Blood PLP concentrations become reduced, and bone marrow ALA synthase as well as ferrochelatase activity is diminished.³⁹ The latter may be secondary to mitochondrial damage by the iron deposits.

The flexed-tail (f/f) mouse has a transient embryonic and neonatal anemia associated with siderotic granules (iron-laden mitochondria) in erythrocytes and reduced heme synthesis, which coincides with the physiologic cessation of hepatic erythropoiesis.^{229,230} The defect is a frameshift mutation in the *f* gene (sideroflexin, *sfxn1*) that encodes a protein proposed to facilitate transport of a component required for iron utilization into or out of mitochondria.²³¹

ACQUIRED CLONAL SIDEROBLASTIC ANEMIA

Since the initial description of acquired idiopathic sideroblastic anemia by Bjorkman,³⁴ a considerable spectrum of its manifestations has been recognized. The anemia is a component of certain stem cell disorders, namely the myelodysplastic syndromes^{50,232,233} and the myeloproliferative diseases.^{234,235,236,237} Uncommonly, the ring sideroblast abnormality has been observed in acute leukemia and in erythroleukemia at the time of diagnosis.^{238,239} The disorder arises in conjunction with the clonal overgrowth of an altered hematopoietic progenitor cell having a proliferative advantage over the normal cell population and, thus, was included among the myelodysplastic syndromes.⁵⁰ Currently three variants are distinguished: refractory anemia with ring sideroblasts (RARS), RARS with thrombocytosis (RARS-T), and refractory cytopenia with multilineage dysplasia and ring sideroblasts (RCMD-RS) (Table 24.1).

Etiology and Pathogenesis

Clonality

The clonal nature of the disorder was first suggested by the morphologic and kinetic findings of two populations of red cells, the hypochromic, short-lived cell population being the product of the abnormal clone that bears the characteristic ring sideroblasts.^{240,241,242} The clonal derivation of the disorder was specifically indicated by the finding of a single glucose-6-phosphate dehydrogenase isoenzyme in hematopoietic cells, but not in fibroblasts, of an individual who was also heterozygous for a glucose-6-phosphate dehydrogenase polymorphism.²⁴³ Further evidence was provided with simultaneous clonality and cytochemical analysis of erythroid progenitors,²⁴⁴ and cytogenetic studies corroborated the clonality of the abnormal hematopoiesis.^{245,246} Chromosomal abnormalities are detectable in bone marrow cells of up to 50% of patients, and deletions in chromosomes 5, 11, and 20 as well as trisomy 8 and loss of Y occur most frequently.^{247,248} Although structurally abnormal X chromosomes are uncommon, Xq13 breakpoints were particularly associated with myelodysplasia and ring sideroblasts in one study.²⁴⁹ Another recurring cytogenetic abnormality is an isodicentric chromosome Xq13.1 (*idicXq13.1*) occurring only in females.²⁵⁰ In a few patients, abnormalities of the long arm of chromosome 3 were associated with thrombocytosis.^{251,252}

More recently it was found that the RARS-T subtype is associated with the V617F mutation in Janus-associated kinase 2 (JAK2), which is common in myeloproliferative disorders,²⁵³ in up to 65% of cases.^{254,255,256} How the more active mutant JAK2, by dysregulating the JAK-STAT (signal transducer and activator of transcription) signaling pathway, may play a role in the pathogenesis of the ring sideroblast, if it does at all, is not known. A strong correlation has also been found between somatic mutations in splicing factor SF3B1, a core component of the RNA splicing machinery located at the U2snRNP spliceosome catalytic site, and the presence of ring sideroblasts in patients with MDS, ranging from an incidence of 57% to 82%.^{257,258,259,260} While mutant SF3B1 thus appears to initiate production of the sideroblastic phenotype, the downstream mechanism(s) leading to the dysregulated iron metabolism in the mitochondrion remains to be identified.^{260a} It has been suggested that the presence of a SF3B1 mutation imparts a "benign" clinical phenotype and favorable prognosis.^{258,260b}

The natural history of this acquired sideroblastic anemia syndrome is commonly characterized by a chronic, stable anemia and, uncommonly, by a progressive marrow failure state or leukemic evolution.^{247,261} An initial genetic change causing expansion of an abnormal hematopoietic clone manifested by defective erythroid cell development is thus insufficient to result in a malignancy, even when persisting for many years. A "second hit" or mutation appears to be necessary for any leukemic evolution²⁶² that can be reversible, whereas the initial manifested defect expressed in the sideroblastic state persists.^{263,264}

Abnormalities in Heme Synthesis

The defective erythropoiesis is characterized at least in part by impaired hemoglobin synthesis, as reflected in the presence of a hypochromic erythrocyte population. Various studies had indicated that the biosynthesis of heme is impaired at the levels of ALA synthase and ferrochelatase. Reduced activity of ALA synthase in marrow cells was the most consistent abnormality in earlier series of patients^{138,265,266} and²⁶⁷ and was particularly demonstrable in the youngest erythroblast fraction.²⁶⁸ In occasional patients, the addition of PLP enhanced the low enzyme activity in vitro, but reported erythropoietic responses to pyridoxine or to PLP administration,²⁶⁹ as well as restoration of low ALA synthase activity to normal,^{265,270} were unusual and may have reflected an inherited defect of ALAS2.^{135,142} In a later study, the activity of detergent-solubilized ALA synthase in bone marrow cells was actually somewhat increased,¹³⁹ suggesting enhanced translation of the enzyme in response to raised cellular iron levels.

A constant feature is mild to moderate elevation of the erythrocyte protoporphyrin,²⁴⁰ rarely reaching values encountered in hereditary protoporphyria^{62,240,242,271} (see Chapter 26). The latter cases may now be explained by a likely acquired deletion of a ferrochelatase allele due to a cytogenetic abnormality of the clonal disorder.²⁷² The erythrocyte protoporphyrin increases further after pyridoxine administration but without improvement of the anemia,^{240,265,273,274} suggesting a block at the ferrochelatase step. Impaired activity of this enzyme was found in approximately one half of patients studied,^{138,267} likely representing a secondary effect of the mitochondrial iron deposition. Studies of iron metabolism in erythroid cells revealed increased accumulation of nonheme iron into membrane or mitochondrial fractions and reduced incorporation of iron into heme.^{8,9} Thus, impaired iron utilization for heme biosynthesis remained the common denominator in the pathogenesis.

Subsequently, a defect(s) intrinsic to mitochondria, causing diminished heme production in the abnormal clone as well as accounting for the decreased activity of several other mitochondrial enzymes (i.e., cytochrome oxidase, oligomycin-sensitive adenosine triphosphatase, and mitochondrial serine protease) in granulocytes and erythroblasts²⁷⁵ was sought. Various heteroplasmic point mutations of conserved nucleotides in mitochondrial DNA, as well as in transfer RNAs and mitochondrial ribosomal RNAs, were found in hematopoietic cells of patients with clonal sideroblastic anemia.^{276,277} Many of these affect cytochrome c oxidase and may be implicated in impaired reduction of iron for its incorporation into protoporphyrin by ferrochelatase. Such mitochondrial defects are consistent with the heterogeneity of hemoglobin content found

P.654

between individual erythroblasts by scanning microspectrophotometry,²⁷⁸ as well as with the variable size of hypochromic microcytic erythrocyte and ring sideroblast cell populations in the disorder. A gradual accumulation of affected erythroid precursors and the known higher mutation rate in mitochondrial DNA than in nuclear DNA would provide a basis for the slowly progressive nature of the anemia and its expression in later life, respectively.

A uniformly reduced transcript of the ABCB7 transporter was observed in 33 patients with RARS²⁷⁹ and may indicate one mechanism leading to this ring sideroblast phenotype. In vitro studies also suggested a link between this ABCB7 down-regulation and SF3B1 mutations²⁸⁰ in association with reduced erythroid development and the aberrant expression of mitochondrial ferritin in CD34⁺ cells that had previously been observed in low-risk myelodysplastic syndromes.²⁸¹

Nuclear Abnormalities

The principal, often macrocytic, red cell population in the blood may represent the progeny of the normal residual erythroid precursors with a shortened marrow maturation time in response to raised erythropoietin levels. The commonly observed morphologic nuclear abnormalities of erythroid precursors and their defective DNA synthesis and mitosis,^{282,283} however, suggest that more viable precursors of the dysplastic clone produce the macrocytic erythrocytes, whereas a greater proportion of developing cells expressing impaired heme synthesis is destroyed in the bone marrow. By analogy, various other aberrations of erythroid cell metabolism can occur in dysplastic hematopoietic clones,²⁸⁴ including altered genetic control of globin chain production. Thus, hemoglobin H disease was acquired in association with erythroleukemia, acute leukemia, and myelofibrosis,²⁸⁵ as well as in sideroblastic anemia with myeloproliferative features²⁸⁶ and in patients with sideroblastic anemia before leukemia developed.²⁸⁷

Iron Overload

Excessive absorption of dietary iron occurs over time in many, if not all, patients with stable disease and can be attributed to the ineffective erythropoiesis, as in congenital sideroblastic anemias and other long-standing disorders with erythroid maturation defects.²⁰ The consequent iron accumulation closely resembles that of hereditary hemochromatosis. Although

the presence of at least one allele for this disorder would likely contribute to the iron overload,²² the incidence of HFE mutations was no greater than in the normal population in most studies.^{22,27,28,288} Inadvertent administration of iron for the anemia and red cell transfusions add predictably to the parenchymal iron deposition.^{184,261,289}

Clinical Features

The disorder usually occurs in middle-aged and older individuals, but younger persons, including children, are not spared. The anemia develops insidiously and may be discovered during a routine examination or in association with an unrelated complaint. The older individual more often experiences symptoms of fatigue and angina if there is coexisting coronary artery disease. Physical examination may reveal no abnormality except for pallor. Hepatosplenomegaly is found in one third to one half of patients. With advanced iron overload, usually after repeated red cell transfusions, symptoms and signs of liver decompensation as well as heart failure and arrhythmia occur.

Laboratory Findings

The anemia is usually moderate and may be normocytic but more often is macrocytic (Fig. 24.6). The mean corpuscular hemoglobin concentration is normal or slightly reduced, and a variable population of hypochromic cells is found on blood smear. A particularly characteristic finding is the presence of occasional basophilic stippling in hypochromic cells that stains positive for iron.^{23,240} Typical Pappenheimer bodies are uncommon unless there is associated hyposplenism or the spleen is absent. Leukocyte and platelet values are usually within the normal range. The presence of the erythroid abnormalities alone constitutes the RARS subtype of the disorder in the World Health Organization (WHO) classification of myelodysplastic syndromes²³³ (see Chapter 73). Associated moderate leukopenia, thrombocytopenia, or both tend to be accompanied by other myelodysplastic features, such as morphologically abnormal leukocytes (e.g., the pseudo-Pelger anomaly) or immature forms in the peripheral blood,²⁴⁷ and define the WHO category RCMD-RS.²³³ The presence of leukocytosis, thrombocytosis, or both is indicative of a mixed myelodysplastic/myeloproliferative disease.^{234,235,236,237}

FIGURE 24.6. Characteristics of the anemia in 17 patients with acquired clonal sideroblastic anemia. Shaded areas, normal range (mean \pm 2 standard deviations). VPRC, volume of packed red cells; MCV, mean corpuscular volume; MCHC, mean corpuscular hemoglobin concentration. (From Kushner JP, Lee GR, Wintrobe MM, et al. Idiopathic refractory sideroblastic anemia. Clinical and laboratory investigation of 17 patients and review of the literature. *Medicine* 1971;50:139-159.)

Erythroid hyperplasia is found on bone marrow examination. A feature claimed to be helpful in distinguishing idiopathic sideroblastic anemia from erythroleukemia is the lack of periodic acid-Schiff (PAS)-positive material in the erythroblasts. Mild megaloblastic changes are common and may or may not be related to accompanying folate deficiency. Marrow hemosiderin content is increased, and ring sideroblasts constitute up to 100% of the erythroblasts unless masked by concomitant iron deficiency.^{2,240,290,291} In contrast to hereditary sideroblastic anemia, ring sideroblasts are evident at all stages of erythroid maturation.¹⁷⁵ Their distinctive expression of mitochondrial ferritin also permits their detection by flow cytometry methods.^{7,292} Because the hematologic phenotype often may be indistinguishable from XLSA in female patients,^{135,136} the analysis of X inactivation status and DNA for ALAS2 defects should be considered.

Serum transferrin saturation is increased in most patients and exceeds 90% in approximately one third of them.²⁴⁰ Substantially increased deposition of iron is found in the liver, but hepatic dysfunction is rare at presentation. Serum ferritin levels are elevated.

Characteristically, the erythrocyte protoporphyrin is moderately increased, up to 300 µg/dl (normal is 20 to 65 µg/dl). Values ranged from 1,055 to 10,514 µg/dl in the patients with probable acquired deletion of one ferrochelatase allele in the hematopoietic clone, and some had associated dermal photosensitivity.^{62,242,271,272}

Treatment and Prognosis

Treatment consists of supportive measures. Pyridoxine administration cannot be expected to be beneficial because ALAS2 defects are not involved in the pathogenesis. Administration of large doses of androgen (e.g., 50 to 300 mg of oxymetholone per day)²⁴⁰ is rarely useful and tends to produce or worsen fluid retention

P.655

and hepatic dysfunction. The effectiveness of erythropoietin has been examined in patients with the myelodysplastic syndromes, including RARS. Most, if not all, patients with uncomplicated sideroblastic anemia have high levels of endogenous erythropoietin, and it would appear unlikely that additional administration of the hormone would be beneficial. However, prolonged administration of recombinant erythropoietin, with or without granulocyte colony-stimulating factor, can lead to gratifying improvement or even correction of the anemia in around 40% of patients,^{293,294} in particular in individuals who have a low or intermediate-1 International Prognostic Scoring System (IPSS) score.²⁹⁵ A response is also more likely to occur if the endogenous serum erythropoietin level is not commensurate with the degree of the anemia,²⁹⁶ and large doses may be required.

Many studies evaluating various drug regimens for the myelodysplasias included the RARS subtypes. The drugs used have included the hypomethylating agents 5-azacytidine and decitabine, anti-tumor necrosis factor (TNF) fusion protein (etanercept), antithymocyte globulin (ATG), thalidomide and its derivative lenalidomide, and valproic acid.^{297,298} and ²⁹⁹ On average, major responses with improved erythropoiesis or hematopoiesis have been less than 50% (see Chapter 73).

Many patients are not significantly incapacitated by the anemia. Without abnormalities of the other hematopoietic cell lines and with minimal iron overload, often no progression occurs for many years.²⁴⁷ Such individuals frequently succumb to other concurrent diseases, but continued medical follow-up is indicated. Iron status should also be assessed with laboratory studies once per year. Transfusion of packed red cells is necessary for patients with symptomatic anemia, but it should be kept to a minimum because it accelerates the iron overload.

Iron overload, particularly when accentuated by repeated transfusions, can be a significant cause of morbidity and mortality (liver failure or heart failure)^{261,300} and is improved with chelation.^{301,302} When the serum ferritin level is approximately 500 µg/L or higher, along with the increased transferrin saturation, it should be countered. Histologic and chemical determination of iron in the liver biopsy provides the optimal assessment of the degree of iron overload. In mildly or moderately anemic individuals, iron removal can be accomplished with graded phlebotomies. Patients with more severe anemia or who are transfusion-dependent require iron chelation as described for congenital sideroblastic anemias. Because each unit of blood deposits 200 mg of iron, iron overload develops fairly rapidly with regular transfusions, and it is controlled more easily if treatment with an iron chelator is begun after approximately 20 units of blood have been given. In some cases, anemia was improved after iron removal^{8,303,304,305}; an independent effect of deferoxamine on erythropoiesis was also implicated.^{304,305}

The survival of patients with isolated anemia who are stable and not transfusion-dependent may not differ from that of healthy individuals. A prospective study of 232 patients, which validated the proposal of the two types of the disorder, provided prognostic information.²⁴⁷ In pure sideroblastic anemia, with the marrow failure restricted to the erythroid cell lineage and now called RARS, overall survival was the same as in age-matched controls, and leukemic transformation was

not observed. In RARS with features of impaired granulopoiesis, megakaryopoiesis, or both, survival was reduced to 56% at 3 years, and, in approximately 5% of cases, evolution to acute leukemia occurred. Other factors associated with the development of leukemia are the presence of few ring sideroblasts, more severe ineffective erythropoiesis, and impaired bone marrow colony formation.^{247,261} The probability of leukemic transformation is also increased in the presence of certain bone marrow karyotype abnormalities (e.g., monosomy 7, deletion 20q, or complex defects).^{247,248,306} When sideroblastic anemia followed therapy for various malignant disorders, leukemic evolution tended to be the rule.^{307,308}

REVERSIBLE SIDEROBLASTIC ANEMIAS

Alcoholism

Anemia associated with alcoholism usually has numerous causes.³⁰⁹ A ring sideroblast abnormality is never the sole cause but occurs in 25% to 30% of anemic alcoholic patients^{310,311} and probably only in the presence of malnutrition and folate deficiency.^{41,311}

The production of heme is impaired by ethanol, as indicated by the ability of heme to restore the concomitantly inhibited globin synthesis in reticulocytes³¹² and by the observation that the heme-regulated inhibitor activity of globin translation increases.³¹³ Inhibitory effects of alcohol have been observed at several steps of the heme biosynthetic pathway. Reduced activity of erythrocyte ALA dehydratase³¹⁴ was believed to be related to zinc depletion.³¹⁵ Activity levels of erythrocyte uroporphyrinogen decarboxylase, leukocyte coproporphyrinogen oxidase, and ferrochelatase are also decreased in alcoholic patients; those of ALA synthase and PBG deaminase are increased.^{314,316} Certain abnormalities of vitamin B₆ metabolism have been observed. Serum levels of PLP are low in chronically ill alcoholic persons³¹⁷ but do not correlate with the presence or absence of ring sideroblasts.³¹¹ Acetaldehyde enhanced the degradation of PLP,^{317,318} and, in one study, alcohol-induced sideroblastic anemia responded to PLP but not to the combination of folic acid and pyridoxine.³¹⁹ The colony formation of early (burst-forming unit-erythroid) and late (colony-forming unit-erythroid) human erythroid progenitor cells is preferentially suppressed by ethanol and acetaldehyde over that of myeloid cell progenitors at concentrations found in vivo and is partially reversed by folic acid and pyridoxine.³²⁰ Thus, a direct role of vitamin B₆ deficiency in the sideroblastic change is uncertain. Important in the pathogenesis may be the direct effects of ethanol, acetaldehyde, or both on the heme biosynthetic steps or on mitochondrial metabolism, because these agents also inhibit hepatic mitochondrial protein synthesis.³²¹

Blood hemoglobin values range from 6 to 10 g/dl, and the MCV is normal or increased. The transient sideroblastic change is commonly evident in dimorphic circulating erythrocytes. Siderocytes, present in approximately one third of patients, are a specific finding³⁰⁹ and provide the most persistent clue for the ethanol-associated ring sideroblast defect. Megaloblastic hematopoiesis resulting from folate deficiency is frequent but is not always present.³⁰⁹ A striking finding is vacuolization of pronormoblasts. The percentage of marrow ring sideroblasts ranges up to 70%, and they typically represent later stage normoblasts.⁴¹ Marrow iron stores usually are increased, as are the serum transferrin saturation and the serum ferritin level.

Withdrawal of alcohol is followed by disappearance of ring sideroblasts within a few days to 2 weeks³¹⁰ (Fig. 24.7). Recovery from the anemia may occur over several weeks and also depends on the presence of other erythroid defects induced by alcohol³¹⁰ as well as any associated medical illness that affects erythropoiesis (see Chapter 41). A prompt recovery phase may exhibit reticulocytosis and erythroid hyperplasia in the bone marrow resembling hemolytic anemia.³¹⁰

Drugs

Antituberculosis Agents

Reversible sideroblastic anemia occurs in association with the treatment of tuberculosis with INH; in a few patients, pyrazinamide and cycloserine also were implicated.³²² These drugs interfere with vitamin B₆ metabolism, and deprivation of PLP reduces ALA synthesis and, thus, heme production.³²² INH reacts with pyridoxal to form a hydrazone and inhibits pyridoxal phosphokinase. Bone marrow ALA synthase activity is also inhibited

P.656

by INH in a dose-dependent manner in vitro and is restored by PLP.¹³⁸ Cycloserine inhibits PLP-requiring enzyme reactions and directly inactivates pyridoxal.³²² Pyrazinamide appears to have anti-vitamin B₆ properties, but a specific mechanism has not been determined.

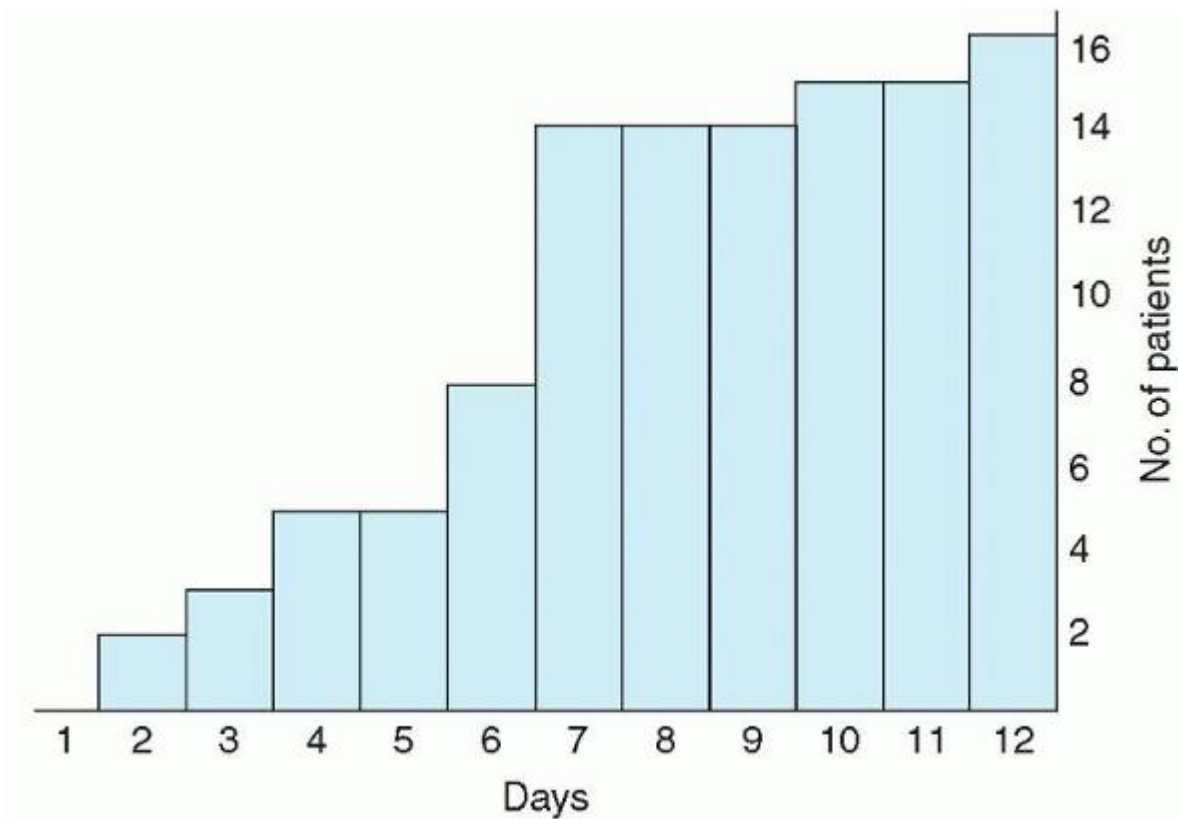

FIGURE 24.7. The rate of clearance in days of ring sideroblasts in 16 alcoholic patients after alcohol intake ceased. (From Eichner ER, Hillman RS. The evolution of anemia in alcoholic patients. *Am J Med* 1971;50:218-232.)

The relative incidence of anemia in relation to the extensive use of these drugs appears to be low, perhaps because of the regular concomitant administration of pyridoxine. Unknown contributory factors or another hematologic disorder may render certain individuals more susceptible to the antipyridoxine effects of the drugs.³²² In one study, ring sideroblasts or increased erythroblast iron was found in 58% of all patients treated for tuberculosis.³²³ Anemia has occurred from 1 to 10 months after institution of INH treatment. It is moderately severe (volume of packed red cells, 0.20 to 0.26 L/L), the red cell indices are usually reduced, and the erythrocytes show dimorphic morphologic features with prominent hypochromia and microcytosis.³²⁴ Ring sideroblasts are invariably present in the bone marrow. Serum pyridoxal concentrations were subnormal in most patients studied.³²⁵ Transferrin saturation tends to be increased. The anemia usually is promptly and fully reversed on withdrawal of the drug or by administering large doses of pyridoxine while continuing use of the drug.

Chloramphenicol and Linezolid

In contrast to the sporadic or idiosyncratic and usually fatal aplastic anemia occurring within weeks or months of chloramphenicol use, the dose-dependent and reversible hematologic toxicity of the drug is predictable and is characterized by suppression of erythropoiesis³²⁶ and by the ring sideroblast abnormality.^{40,327} A primary mitochondrial injury by the agent impairs heme synthesis as well as erythroid differentiation and proliferation. Therapeutic concentrations of chloramphenicol (10 µg/ml) inhibit the synthesis of mitochondrial membrane proteins, such as cytochrome $a + a_3$ and b , and, thus, mitochondrial respiration.^{328,329} Impaired heme synthesis is evident in reduced activities of ferrochelatase³³⁰ and ALA synthase,³³¹ which appear to be secondary effects as these enzymes are synthesized in the cytosol. The greater sensitivity of erythroid cells to chloramphenicol has been demonstrated *in vitro*, in that therapeutic concentrations of the drug inhibit erythroid colony growth but not granulocyte colony growth.³³²

The anemia may reach moderately severe levels. Bone marrow study reveals variable degrees of hypocellularity and ring sideroblasts as well as prominent vacuolization of early erythroid precursors. Erythrokinetic parameters reflect a hypoproliferative state. Reticulocytopenia, increased serum iron values, and prolonged plasma iron clearance are characteristic.³²⁶ These abnormalities, as well as the ring sideroblasts and anemia, disappear upon withdrawal of the drug.

Linezolid causes reversible myelosuppression and the ring sideroblast abnormality has also been observed.³³³ Its toxicity resembles that of chloramphenicol in that it inhibits mitochondrial protein synthesis (mRNA translation), although it

blocks assembly of the initiation complex, while chloramphenicol inhibits peptidyl transferases and thus peptide elongation.³³⁴ Vacuolization of erythroid precursors is common, and the hematologic abnormalities disappear upon discontinuation of the drug.

Other Drugs

Several miscellaneous drugs have been implicated in producing sideroblastic anemia in a few patients. These include fusidic acid, busulfan, melphalan, penicillamine and triethylene tetramine dihydrochloride.

Copper Deficiency

Deficiency of copper generally does not occur in humans because requirements are low relative to its wide distribution in food.³³⁵ However, copper deficiency anemia is encountered in various clinical settings and typically leads to sideroblastic anemia and neutropenia. It has developed after prolonged parenteral nutrition^{45,46,336,337} and forced enteral feeding^{338,339} if copper was not included in the formulations, and in association with intestinal malabsorption³⁴⁰; some patients have had prior gastrointestinal operations, e.g., gastrectomy, bariatric surgery.^{341,342} Copper deficiency also occurs with the use of copper-chelating agents³⁴³ and after prolonged ingestion of zinc, such as in the form of zinc supplements³⁴⁴ and with the chronic use of denture cream containing zinc.^{345,346} In six instances, the deficiency developed from ingestion of coins and was attributed to their zinc content.^{347,348,349,350} and³⁵¹

A novel syndrome of severe sideroblastic anemia with the neurologic manifestations of central nervous system demyelination, or peripheral neuropathy with optic neuritis, or myelopathy and profound copper deficiency was recognized only 10 years ago^{352,353,354} and was proposed to represent another combined system disorder resembling vitamin B₁₂ deficiency.³⁵⁵ Subsequently numerous cases with this syndrome were reported.³⁴¹ In some, excess zinc ingestion was present and not infrequently remote prior gastric resection was noted.³⁴¹ Myeloneuropathy has been the most frequent neurologic abnormality.

The pathogenesis is understood in part from extensive studies of the severe anemia that develops late in the course of dietary copper deficiency in swine.³⁵⁶ In these animals the anemia is microcytic and hypochromic and is associated with several defects of iron metabolism. Intestinal absorption and mobilization of iron from reticuloendothelial cells and hepatocytes to transferrin are impaired because of the associated lack of ceruloplasmin (ferroxidase). In reticulocytes of deficient animals, protoporphyrin production from glycine and ALA and ferrochelatase activity are not reduced,³⁵⁷ but iron metabolism in erythroid mitochondria is impaired in that heme synthesis from ferric iron and protoporphyrin is decreased.³⁵⁸ It was postulated that the reduction of ferric iron to ferrous iron is defective, being somehow linked to the diminished levels of cytochrome oxidase also observed. Low levels of intracellular copper enzymes, such as cytochrome oxidase, may interfere with hematopoiesis in other ways and also account for the neutropenia as well as the neuropathology in humans. The cause of copper deficiency after ingestion of excess zinc has been attributed to induction of the intestinal protein metallothionein by zinc,³⁵⁹ which preferentially binds copper,³⁶⁰ prevents its absorption, and enhances its excretion.³⁶¹

The anemia is progressive and may be profound if untreated. The MCV usually is normal or slightly increased at presentation;

P.657

hypochromic microcytic erythrocytes may be detectable on the blood smear. The granulocytes are commonly $<1,000/\text{mm}^3$; the platelet count is usually normal. The bone marrow tends to be hypoplastic, with impaired myeloid maturation.^{45,46} Vacuolization of early erythroid and granulocytic precursors is a prominent finding, as are large iron-positive cytoplasmic inclusions in plasma cells.^{45,354} In most instances, moderate numbers of ring sideroblasts are observed, in particular if the anemia is sufficiently severe. The hematologic features have occasionally led to the erroneous diagnosis of a myelodysplastic syndrome before the copper deficiency was recognized.^{354,362,363}

Serum iron levels and transferrin saturation are normal. The serum copper and ceruloplasmin levels are uniformly low. In cases of zinc-induced copper deficiency, serum zinc levels are increased from two- to threefold above the mean normal value.

With correction of the copper deficit, recovery of the hematologic abnormalities is uniformly prompt and complete. In some cases, recovery followed discontinuation of the excess zinc intake alone. Zinc as a therapeutic agent should thus be prescribed with caution,^{364,365} and its use as a stimulus for general well-being should be discouraged. Moreover, the zinc content has been removed from denture cream products. The neurologic abnormalities may improve or only stabilize with

continued copper supplementation.^{341,353,354,362} The usual dose of copper may not be sufficient for all patients as relapse has occurred,³⁶⁶ and longterm follow-up is advised for all patients.

Hypothermia

In 1982, O'Brien et al. described three patients who, during episodic hypothermia, exhibited erythroid hypoplasia and ring sideroblasts as well as thrombocytopenia in the presence of a normal number of megakaryocytes.⁴⁸ As the body temperature returned to normal, these changes slowly reversed. The ring sideroblast abnormality might be explained by the well-known inhibition of the translocation of proteins into mitochondria by reduced temperature.^{48,367} Heme synthesis³⁶⁸ and iron incorporation into hemoglobin by reticulocytes³⁶⁹ have also been shown to be diminished at lowered temperatures.

ANEMIA FROM DEFECTS IN ERYTHROID HEME SYNTHESIS WITHOUT RING SIDEROBLASTS

Anemia of Lead Poisoning

Lead poisoning has occurred from a wide array of sources, including lodged bullets, inhaled fumes in various industries or lead particles in a firing range, ingested contaminated herbs and food supplements, and beverages containing lead solubilized from glazes of utensils and linings of stills.^{370,371} In children, the primary source was ingestion of lead-based paint chips. Organic lead is acquired by absorption through the skin or by gasoline sniffing. Heterozygotes of hereditary ALA dehydratase deficiency are said to be more susceptible to lower levels of lead exposure,³⁷² as are persons with one or both genes for the less common allele (ALAD2) of the enzyme.³⁷³ Although lead has been eliminated from various consumer products and occupational exposure is monitored, it may still remain the most common cause of occupational poisoning worldwide.³⁷⁴

The anemia that accompanies lead poisoning (plumbism) is in part the result of various inhibitory effects of lead on heme biosynthesis.^{375,376} Most enzymes in the heme biosynthetic pathway are inhibited by lead to varying degrees. Presumably, lead displaces an essential metal or reacts with active-site thiol groups of the enzymes, but the precise mechanism is not worked out in most cases. ALA dehydratase is most sensitive to lead *in vitro* and *in vivo*, followed by ferrochelatase, coproporphyrinogen oxidase, and PBG deaminase, respectively. The effects of lead on the production of heme are also interrelated with iron metabolism. In erythroid cells, lead impedes the intracellular delivery of iron to waiting ferrochelatase, and the surrogate metal zinc is inserted into protoporphyrin by ferrochelatase as in iron deficiency³⁷⁷ so that zinc protoporphyrin accumulates. These events probably account for the usual absence of the ring sideroblast abnormality in persons with lead intoxication. Ferrochelatase may be directly inhibited in acute and more severe lead intoxication, and, only then, nonchelated protoporphyrin accumulates in erythrocytes.^{378,379} Lead also impairs globin synthesis.³⁸⁰ With prolonged lead exposure, erythroid hypoplasia may occur.³⁸¹

Other effects of lead increase the rate of red cell destruction. Changes in the spatial arrangement of red cell membrane proteins caused by lead are believed to inhibit adenosine triphosphatase, leading to cellular loss of K^+ .³⁸² If the lead burden is sufficiently severe (i.e., with blood lead concentrations of 200 $\mu\text{g}/\text{dl}$ or greater), impaired erythrocyte pyrimidine 5'-nucleotidase activity causes accumulation of nucleotides that inhibit the pentose phosphate shunt³⁸³ and promote hemolysis as in the genetically determined deficiency of the enzyme (see Chapter 28).

The typical clinical manifestations are autonomic neuropathy causing abdominal pain and ileus (lead colic) and motor neuropathy (lead palsy).³⁸⁴ A lead line may be seen on the gums and tonsils. Occasionally, renal dysfunction (lead nephropathy) may prompt the diagnosis. These classic features denote advanced lead toxicity, and more common are insidious, nonspecific musculoskeletal and neuropsychiatric complaints.³⁷⁰

The hematologic changes in lead poisoning are variable and can be attributed to the multiplicity of toxic actions on the erythron. More recently, anemia was present in only 25% of adult patients.³⁷⁰ Anemia in children is also a late sign of lead poisoning by current standards³⁸⁵ and frequently is superimposed on pre-existing iron deficiency.³⁸⁶ The severity of the anemia ranges from mild to moderate, and the red cells tend to be mildly hypochromic and microcytic (Table 24.4). The reticulocyte count may be raised in patients with overt hemolysis.³⁸⁴ Coarse basophilic stippling may be prominent (Fig. 24.8), representing polysomal aggregates that presumably are retained because RNA degradation is impaired as a result of the pyrimidine 5'-nucleotidase deficiency, but it is not always present and does not correlate with the lead burden.^{385,387} Osmotic fragility of the erythrocytes is decreased; mechanical fragility is increased consequent to the membrane injury.³⁸⁷ An electrophoretically "fast" hemoglobin similar to hemoglobin A₃ may be found.³⁸⁸ The bone marrow usually reveals erythroid hyperplasia, but it may be hypoplastic. Authentic ring sideroblasts are uncommon, if they occur at all.

The mean red cell life span is reduced with a random pattern of destruction despite problems with the accelerated ⁵¹Cr elution from red cells due to lead effects on the red cell membrane.³⁸⁹ Serum iron levels tend to be normal or slightly

increased unless the patient has associated iron deficiency. The findings of ferrokinetic studies are consistent with ineffective erythropoiesis accompanied by mild hemolysis.³⁸⁹

Parameters of heme biosynthesis reflect the inhibition of the various enzymatic steps and correlate with the lead burden.³⁷⁵ ALA dehydratase activity in erythrocytes is reduced in proportion to blood lead levels, and, in contrast to the hereditary deficiency of the enzyme, its in vitro activity is restored to normal by reducing agents such as glutathione or dithiothreitol.³⁷⁵ As a consequence of the reduced activity, urinary ALA is greatly increased, whereas levels of PBG are rarely increased, a combination that distinguishes plumbism from acute porphyrias, in which PBG is excreted in greater excess than ALA. Urinary coproporphyrin, and to a lesser degree uroporphyrin, levels are also increased in

P.658

lead poisoning. The zinc protoporphyrin level in erythrocytes is increased more than in iron deficiency.

TABLE 24.4 HEMATOLOGIC CHANGES IN THE ANEMIA OF LEAD POISONING IN ADULTS

		Normal (Range)	Lead Poisoning (Range)
Hemoglobin (g/dl)	Male	14.0-18.0	10.7
	Female	12-16	8-13
Volume packed red cells (L/L)	Male	0.40-0.54	0.35
	Female	0.37-0.47	0.29-0.43
Mean corpuscular volume (fl)		89 (83-96)	79 (70-92)
Mean corpuscular hemoglobin concentration (g/dl)		34 (32-36)	31 (27-36)
Reticulocytes (%)		1.6 (0.6-2.7)	4.4 (1.5-11.6)
Stippled cells (%)		Rare	1.8 (0.1-7.5)
Leukocytes ($\times 10^9/L$)		4-11	4-15

Adapted from Dagg JH, Goldberg A, Lochhead A, et al. The relationship of lead poisoning to acute intermittent porphyria.

QJM 1965;34:163-175 and Griggs RC. Lead poisoning: hematologic aspects. Prog Hematol 1964;4:117-137.

The upper limit of the "normal" level of blood lead, which is mostly contained in erythrocytes, is 30 $\mu\text{g}/\text{dl}$ of whole blood. Adults with concentrations of 30 to 75 $\mu\text{g}/\text{dl}$ show decreased ALA dehydratase activity, increased urinary excretion of ALA, and an increase in erythrocyte protoporphyrin,³⁹⁰ and may have nonspecific symptoms of lead poisoning. Clear symptoms usually are associated with concentrations that exceed 75 $\mu\text{g}/\text{dl}$. Concentrations in urine >0.1 mg/24 hours also establish the diagnosis of lead intoxication. When urinary lead excretion is borderline, response to slow intravenous infusion of 25 mg/kg (not to exceed 2 g) of the chelator calcium disodium ethylenediaminetetraacetic acid can confirm the diagnosis; excretion of more than 0.2 mg of lead in 24 hours indicates an increased lead burden.

Treatment consists of removal of the lead source and administration of ethylenediaminetetraacetic acid, 50 mg/kg/day in two divided doses, by slow intravenous infusion with ample fluids for 5 days.^{371,390} This regimen may be repeated in 3 to 4 weeks, depending on the response of blood lead levels. Renal function should be monitored. Recovery usually is prompt. An oral chelating agent, 2,3-dimercaptosuccinic acid, is also available.³⁹¹

Certain Porphyrias

Heme biosynthesis is strikingly perturbed in the various porphyrias that result from heterogeneous molecular defects in each of the enzymes in the pathway (see Chapter 26). Tissue-specific differences of expression and of regulation of these enzymes likely account for the absence of anemia in most porphyrias, as the defective enzymes do not become rate-limiting in the erythroid cell. In a few of them, erythroid heme production may be minimally compromised, as noted for protoporphyria previously; or accumulation of biosynthetic intermediates perturbs erythroid cell development, survival, or both.

FIGURE 24.8. Hypochromia and red cell stippling in lead poisoning.

Congenital Erythropoietic Porphyria

In this rare disorder, expressed as an autosomal recessive trait, erythroid heme biosynthesis is not diminished.^{392,393} Because of the low residual uroporphyrinogen III synthase activity, uroporphyrin I accumulates, mainly in erythroid cells. Variable anemia is associated with dyserythropoiesis and varying degrees of peripheral hemolysis. The porphyrin accumulates in the nuclei of developing erythroblasts and is believed to affect their maturation. Anemia often is not the principal clinical problem. In some patients, the hemolytic process was improved by splenectomy.

Hepatoerythropoietic Porphyria

Hepatoerythropoietic porphyria represents the homozygous deficiency of uroporphyrinogen decarboxylase and is expressed as a variably severe form of porphyria cutanea tarda typically manifesting during infancy or early childhood.³⁹⁴ About 40 cases have been reported, and anemia was noted in more than 50% of patients.³⁹⁵ Severe anemia or a hemolytic process is the exception. The level of erythrocyte protoporphyrin, primarily as zinc protoporphyrin, is increased and is attributed to a relatively increased conversion of uroporphyrinogen III to protoporphyrin late in erythroid maturation when iron supply may become rate limiting. The anemia has not been characterized.

Harderoporphyria

Anemia has been encountered in this erythropoietic variant of hereditary coproporphyria, in which large amounts of the tricarboxylic harderoporphyria accumulate.^{396,397,398} Affected individuals carry distinctive homozygous or compound heterozygous mutations in the coproporphyrinogen III oxidase gene, and the mutant enzyme has 18% to 24% residual activity.³⁹⁷ Clinically, neonatal hemolytic anemia with hyperbilirubinemia and hepatosplenomegaly is followed by mild microcytic anemia and variable photosensitivity in adulthood. Neurovisceral symptoms of acute porphyria may occur.³⁹⁸ Expression of the defect is usually limited to erythroid tissue and is characterized by impaired heme synthesis and dyserythropoiesis with associated iron overload.³⁹⁷

P.659

KEY CLINICAL SUMMARY POINTS

• General Definition of Sideroblastic Anemia (SA)

Sideroblastic anemia comprises a wide spectrum of heritable or acquired erythropoietic disorders. Regardless of clinical and peripheral blood abnormalities, the unifying feature of all forms of SA is the presence of bone marrow ring sideroblasts.

• Prompt Diagnosis of a Sideroblastic Anemia

Consider in all adults and children/infants with unexplained anemia of any severity from history, clinical examination, and basic laboratory data. Certain features are suggestive: history of chronic anemia; exposure to factors causing reversible SA (Table 24.1); family history of anemia; presence of neurologic abnormalities, myopathy, lactic acidosis, immunodeficiency in children or young adults.

Suspect a congenital SA in the presence of microcytosis without evidence of iron deficiency or thalassemia; the MCV and erythrocyte morphology are most accurate before any red cell transfusion (Fig. 24.9).

Establish the diagnosis of SA by performing a Prussian blue stain on the bone marrow aspirate smear.

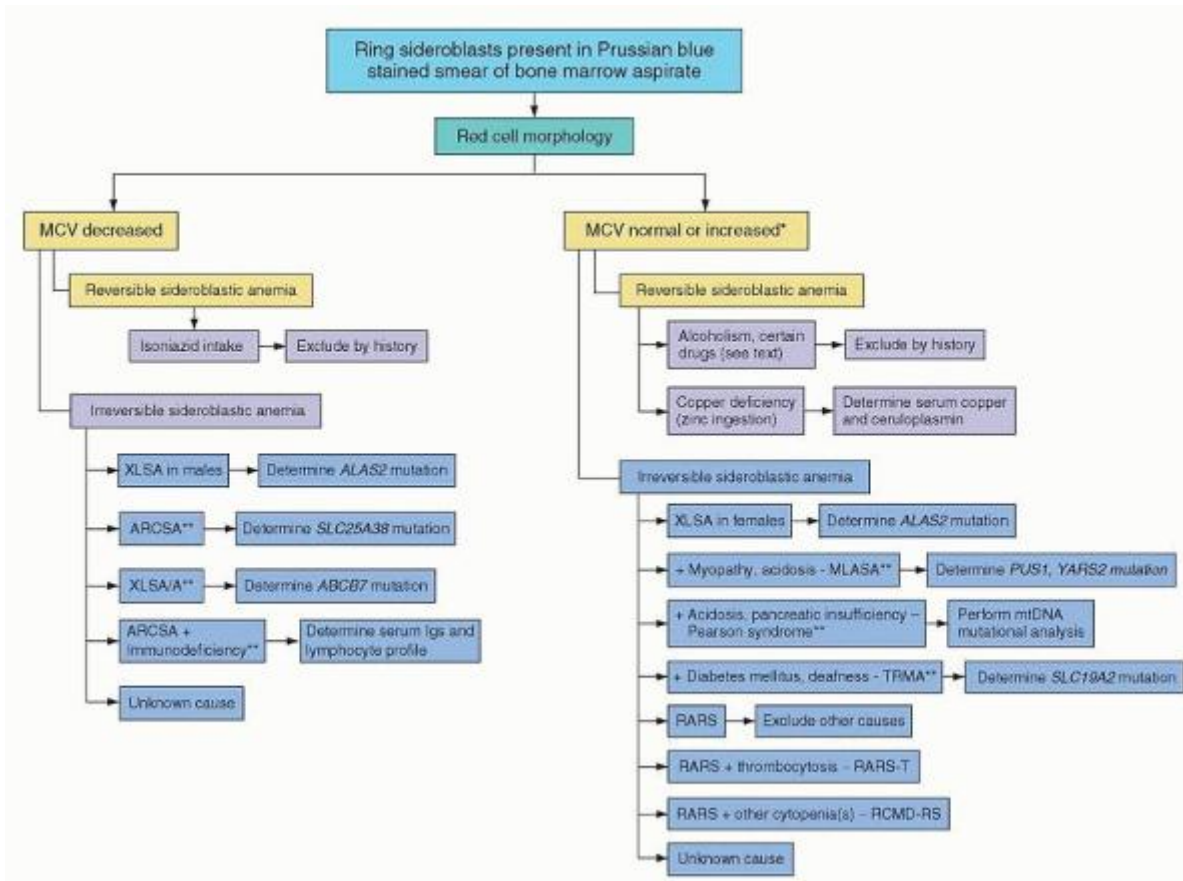

FIGURE 24.9. Schema for diagnostic evaluation of patients with a sideroblastic anemia. MCV, mean corpuscular volume; XLSA, X-linked sideroblastic anemia; ARCSA, autosomal recessive sideroblastic anemia; XLSA/A, X-linked sideroblastic anemia with ataxia; Igs, immunoglobulins; MLASA, myopathy, lactic acidosis, and sideroblastic anemia; mtDNA, mitochondrial DNA; TRMA, thiamine-responsive megaloblastic anemia. *Microcytic hypochromic red cells may be present in the blood smear in many, but not all, of these disorders. **Typically present in infancy or childhood.

• Differential Diagnosis

If ring sideroblasts are evident in the marrow, review the patient's constellation of clinical findings to narrow the differential diagnosis (Table 24.1, Fig. 24.9).

Where the causative gene is known, mutation analysis provides definitive diagnosis of a congenital SA; some molecular genetic tests are available in several clinical laboratories listed on the www.genetests.org website, others may be available in certain research laboratories.

Evaluate for iron overload with serum iron profile and ferritin; assess parenchymal organ involvement as indicated.

- Treatment

Withdraw an identified reversible cause.

Recommend a therapeutic trial of pyridoxine (adult dose 50 to 100 mg/day) in patients with microcytic SA until the genetic cause can be determined; the vitamin is only effective in some cases with XLSA.

For symptomatic anemia, provide supportive treatment with red cell transfusion.

Remove excess body iron by phlebotomy if anemia is mild; by use of iron chelation in patients with severe/transfusion-dependent anemia.

P.660

Prescribe thiamine (25 mg/day) in the TRMA syndrome.

Manage the clinical aberrations associated with the syndromic forms of congenital SA with available supportive measures.

- Follow-up

Educate the patient and family about the disease and relevant inheritance.

Encourage patients to keep records of diagnostic studies and recommended therapy.

In cases with congenital SA, provide for examination of family members and for their genetic testing as indicated.

Chapter 25

Hemochromatosis

Corwin Q. Edwards

James C. Barton

IRON OVERLOAD

Iron overload can result from any process that causes iron accumulation in excess of iron loss. Examples of such processes include (a) erythrocyte transfusions in individuals who do not experience blood loss (e.g., patients with hemolytic anemia, aplastic anemia, and sideroblastic anemia); (b) absorption of excessive amounts of normal dietary iron (hemochromatosis types 1 through 4, disorders of ineffective erythropoiesis); and (c) absorption of increased amounts of excessive dietary iron (e.g., high-dose medicinal iron and African iron overload).

Definition

The definition of iron overload typically includes a description of an individual's iron phenotype, such as (a) an elevated serum ferritin concentration; (b) excessive iron in the liver or myocardium (estimated histologically or by chemical methods); and (c) the requirement of a greater than normal number of phlebotomies to induce iron-limited erythropoiesis.

HEMOCHROMATOSIS

Hemochromatosis Type 1, HFE Hemochromatosis

The definition of “classical,” autosomal recessive hemochromatosis (type 1) typical of Western European whites once required demonstration of the rare triad of cutaneous hyperpigmentation (“bronzing”), diabetes mellitus, and cirrhosis that was presumed to represent complications of severe iron overload. The eventual ability to measure iron in liver and other tissues, serum, and by phlebotomy to achieve iron depletion revealed that hemochromatosis was more common than previously believed and that the diagnosis could be defined by severity of iron overload. In 1996, it was discovered that most patients with this type of hemochromatosis were homozygous for a common missense mutation (C282Y) of the HFE gene on chromosome 6p21.3. Thus, most current definitions of hemochromatosis in Western European whites include specification of the iron phenotype and HFE genotype. Three important relationships of phenotype and genotype definitions are: (a) HFE C282Y homozygosity is a genetic configuration that markedly increases the risk that iron overload will eventually develop without other readily demonstrable cause; (b) iron phenotypes and organ-specific complications of HFE C282Y homozygotes vary greatly due to genetic and environmental factors; and (c) iron overload, not HFE C282Y homozygosity or abnormal HFE protein, causes tissue injury in target organs.

Hemochromatosis Type 2, Juvenile Hemochromatosis

Hemochromatosis type 2 is characterized by nontransfusion iron overload, often severe, that typically occurs in children or young adults.

Type 2a, Mutations of Hemojuvelin Gene (HJV)

Hemochromatosis type 2a is an autosomal recessive disorder due to pathogenic mutations in the hemojuvelin gene (HJV; chromosome 1q21).^{1, 2} The iron overload phenotype of patients with HJV hemochromatosis is much more severe at the same age than the phenotype of typical patients with hemochromatosis due to HFE C282Y homozygosity and the penetrance of hemochromatosis type 2a genotypes (risk to cause iron overload) is also greater. Hemochromatosis type 2a often causes abdominal pain and hepatomegaly in children, hypogonadotrophic hypogonadism in teenagers, arthropathy, and severe heart failure, cardiac arrhythmias, and cirrhosis before the age of 30 years.³ Based on the volume of blood removed to achieve iron depletion in some patients, it can be deduced that they absorbed 3.2 to 3.9 mg of dietary iron per day.⁴ In severe HFE hemochromatosis, 2 mg of iron or less is absorbed daily.^{5, 6}

Two pathogenic HJV mutations (either homozygous or compound heterozygous configuration) occur in each patient. The most common HJV mutation causes a change in nucleotide 959G→T, which codes for substitution of the normal glycine by valine in position 320 of the polypeptide sequence of the HJV protein (HJV G320V). This mutation has been detected in patients with juvenile-onset hemochromatosis of diverse European ethnicities.^{7, 8} About 30 pathogenic HJV mutations have been reported. Many are novel (not detected in unrelated patients with hemochromatosis type 2a.)^{7, 8, 9, 10, 11} Some HJV hemochromatosis patients also have an abnormal HFE genotype but the latter does not account for iron overload in most cases.¹²

Hemojuvelin is involved in the up-regulation of hepcidin synthesis, not in the regulation of HFE function. Decreased hemojuvelin activity decreases hepcidin synthesis, thus decreasing hepcidin binding and inactivation of ferroportin. Consequently, regulation of iron transport out of absorptive enterocytes into the plasma via ferroportin is decreased, even in the presence of increased storage iron.

Type 2b, Mutations of Hepcidin Gene (HAMP)

Hemochromatosis type 2b is associated with iron overload of variable severity and age of onset and is also transmitted as an autosomal recessive trait.^{12, 13} This disorder is rare. Hemochromatosis type 2b is due to mutations in the hepcidin gene (HAMP, chromosome 19q13). HAMP is an acronym for hepcidin antimicrobial peptide. The word hepcidin is derived from hepatic bactericidal protein.

The first reported HAMP mutation (nucleotide 208T→C) causes substitution of the normal cysteine by arginine at amino acid 70 (C70R).¹⁴ Approximately 12 other HAMP mutations have been reported.^{15, 16, 17, 18} Mutant hepcidin has decreased ability to bind to ferroportin, its only receptor. Consequently, ferroportin is not degraded and thus continues to transport iron across the basolateral membrane of absorptive enterocytes in the presence of excess iron stores.¹⁹ Some hemochromatosis type 2b patients, usually those heterozygous for pathogenic HAMP promoter or coding region mutations, also have HFE mutations that contribute to the pathogenesis of iron overload ("digenic" hemochromatosis).

Hemochromatosis Type 3, Mutations of Transferrin Receptor-2 Gene (TFR2)

Hemochromatosis type 3 is a rare autosomal recessive disorder reported in persons of European or Asian ancestry caused by mutations of the transferrin receptor-2 gene (TFR2) located on chromosome 7q22.²⁰ The clinical phenotype is moderately variable and resembles either that of HFE hemochromatosis or that of juvenile hemochromatosis types 2a and 2b. Fewer than 20 pathogenic TFR2

P.663

mutations have been reported.^{20, 21, 22, 23, 24} The penetrance of hemochromatosis type 3 genotypes is relatively great. Consanguinity has been identified in some affected families. TFR2 Y250X and R455Q have been detected in individuals or kindreds who were not closely related.²⁰ Pathogenic TFR2 mutations either result in gain-of-function or in decreased quantities of functional transferrin receptor-2. TFR2 protein is thought to modulate the signaling pathway that controls hepcidin expression²⁵ with consequent low hepcidin²⁶ and increased iron absorption and deposition in hepatocytes.

Hemochromatosis Type 4, Mutations of Ferroportin Gene (SLC40A1)

Hemochromatosis type 4 is an uncommon heterogeneous disorder transmitted as an autosomal dominant trait. It is caused by mutations of a gene of the solute carrier family 40 (member #1) (SLC40A1, chromosome 2q32), which encodes the synthesis of ferroportin, the sole receptor of hepcidin.^{27, 28, 29, 30} There are two distinct ferroportin hemochromatosis phenotypes. Loss-of-function SLC40A1 mutations encode ferroportin that either is not presented normally to the cell surface or has defective iron transport activity. Such mutations decrease iron absorption from the intestine and inhibit iron egress from macrophages. Phenotypes of affected patients include normal or low transferrin saturation, mild anemia, and predominance of iron retention in macrophages. Gain-of-function mutations encode ferroportin that cannot bind hepcidin normally or be internalized after hepcidin binding (hepcidin resistance). This increases iron absorption and

stimulates iron export by macrophages. Affected patients have elevated transferrin saturation and iron deposition in hepatocytes.

Ferroportin mutations are cosmopolitan. Most reported mutations are restricted to single families. SLC40A1 V162del has been reported in persons with iron overload from Australia, Europe, and Asia. SLC40A1 A77D has been reported in persons with iron overload in Italy, Australia, and India. SLC40A1 Q248H occurs as a polymorphism in natives who reside in diverse areas of sub-Saharan Africa and in African Americans, but probably does not cause iron overload.³¹

HISTORY

Hemochromatosis Type 1, Classical, Hereditary

The first report of a person with hemochromatosis was included in a discussion of diabetes mellitus in 1865.³² The patient was a 28-year-old Parisian man who sold newspapers and who died of a febrile illness that complicated his diabetes. His autopsy revealed hepatomegaly and hypertrophic cirrhosis. The second case of hemochromatosis was reported in 1871 and described a 51-year-old man who lived in Paris.³³ He had skin bronzing of his face and hands. His autopsy revealed a chocolate-colored, enlarged liver. Microscopic examination of his liver showed pigment granules inside and outside of hepatocytes. In 1886, the term pigmentation cirrhosis was used to describe the triad of skin bronzing, diabetes mellitus, and hepatic cirrhosis.³⁴ The name hämochromatose was first used by von Recklinghausen in his 1889 description of 12 individuals who had pigmentation of multiple organs.³⁵ He believed that the iron that accumulated in organs came from red blood cells.

ETIOLOGY

Cloning of the HFE Gene

In 1996, the hemochromatosis gene was isolated by positional cloning and two common mutations that account for most cases of hemochromatosis in persons of Western European descent were discovered.³⁶ The gene was named HFE (H = hemochromatosis; Fe = iron).^{37, 38} The cloning of HFE was reported more than 130 years after the first case description of hemochromatosis at autopsy and confirmed reports during an interval of more than two decades that hemochromatosis was transmitted as an autosomal recessive condition linked to the HLA locus on the short arm of chromosome 6.^{39, 40, 41, 42, 43, 44, 45, 46, 47}

Function of the HFE Gene

The normal HFE gene encodes normal HFE protein which is expressed in duodenal crypt cells and reticuloendothelial cells.⁴⁸ In a normal individual, HFE protein binds to β_2 -microglobulin, which decreases the affinity of cell membrane transferrin receptors for transferrin.^{49, 50, 51, 52} This decreases iron absorption. In iron deficiency, HFE protein synthesis is decreased, binding of HFE protein to β_2 -microglobulin is decreased, the affinity of the transferrin receptor for transferrin is increased, and thus duodenal crypt cells absorb more iron.

Effects of HFE Gene Mutations

The HFE protein binding site for the β_2 -microglobulin binding site has two cysteine molecules that form a disulfide bridge. In HFE C282Y homozygotes, tyrosine replaces a cysteine molecule at amino acid position 282 in the product of both HFE gene copies (maternal and paternal) and thus the disulfide bridge is absent. This prevents binding of the abnormal HFE protein to β_2 -microglobulin on the cell surface. Excessive iron is then absorbed through the crypt cells and passed into the circulation.^{53, 54, 55, 56, 57, 58} Despite these observations, the full function and participation of the HFE protein in iron absorption has not been elucidated. Studies of penetrance of hemochromatosis demonstrate that HFE C282Y homozygosity is necessary but probably not sufficient for iron overload to develop.

PATHOPHYSIOLOGY

Normal adults absorb an amount of iron each day that precisely balances daily losses (men ~1 mg, women 1 to 3 mg). In healthy children and infants, daily iron absorption corresponds to the iron requirements of growth and development. In acute blood loss or iron deficiency, daily iron absorption increases until the total body deficit has been replaced. In persons with hemochromatosis, the absorption of dietary iron is inappropriately great in comparison with quantities of total body iron. In some persons with HFE hemochromatosis and iron overload, daily iron absorption may exceed 2 mg at a time when iron absorption should have decreased to nearly zero.^{59, 60} In some children with juvenile hemochromatosis, average daily iron absorption may exceed 3 mg/day. Phlebotomy therapy to achieve iron depletion in hemochromatosis may increase iron absorption to 10 mg/day and iron absorption may remain inappropriately elevated long after iron deficiency resolves.^{61, 62, 63} Iron loading in hemochromatosis types 1 to 4 is caused either by an abnormality in hepcidin

synthesis or a decrease of its activity via decreased function of ferroportin. HFE, HJV, and TFR2 probably all have a contributory role in regulating hepcidin synthesis.

Effects of Hepcidin

Hepcidin, the central regulator of iron absorption, is a low-molecular-weight thionin-like, defensin-like peptide with many cysteine pairs encoded by the HAMP gene. Hepcidin has antimicrobial activity against bacteria and fungi, is present in plasma, and is excreted in urine. Hepcidin is synthesized in hepatocytes in response to anemia, hypoxia, and inflammatory stimuli mediated by interleukin 6,^{64, 65, 66, 67, 68, 69, 70, 71} and in the presence of adequate or increased amounts of iron.^{72, 73, 74, 75} It is also involved in the abnormalities of iron metabolism that occur in the anemia of chronic disease.^{76, 77, 78, 79} Hepcidin levels are inversely related to iron absorption.

P.664

Ferroportin, the sole receptor for hepcidin, occurs as a multimer on the surfaces of cells responsible for gathering and recycling iron: enterocytes (basolateral surfaces), macrophages, hepatocytes, and placental syncytiotrophoblasts. The binding of cell surface ferroportin by hepcidin results in ferroportin tyrosine phosphorylation at the plasma membrane, dephosphorylation, and degradation by ubiquitination.^{19, 69, 80} Thus, hepcidin participates in regulation of plasma iron levels and tissue distribution of iron by post-translational regulation of ferroportin.

Hepcidin Effect in Iron Deficiency

In iron deficiency, hepcidin production is down-regulated so the amount of hepcidin available to bind ferroportin is reduced. More iron is exported from absorptive enterocytes by ferroportin than usual, resulting in increased absorption of iron through duodenal enterocytes into the plasma.⁸¹

Hepcidin Effect in Iron Repletion

In normally iron-replete humans, the production of hepcidin is up-regulated. The hepcidin binds with ferroportin inducing ferroportin internalization and degradation.^{19, 69, 80} Consequently, the amount of ferroportin is reduced and iron absorption from duodenal enterocytes into plasma decreases.

Hepcidin Effect in Hemochromatosis

Dysregulation of hepcidin production underlies the pathophysiology of most types of hemochromatosis (types 1, 2a, 2b, and 3). In iron-loaded individuals with HFE hemochromatosis, for example, hepcidin expression by the liver is inappropriately low^{82, 83} and thus iron absorption continues despite increased iron stores. Hepcidin levels are decreased in all types of hemochromatosis except in patients with "classical" ferroportin hemochromatosis (type 4). In those patients, iron overload is caused by a mutation in the ferroportin gene (SLC40A1) that results in diminished or absent functional quantities of ferroportin.⁸¹ In such cases, hepcidin production and regulation are normal.

Molecular Basis of Increased Iron Absorption in Hemochromatosis

Several factors in the duodenum contribute to inappropriately high iron absorption in HFE hemochromatosis. In enterocytes, DMT1 (divalent metal transporter-1) transports iron across the apical microvillous membrane into the cell in the presence of hydrogen ions derived from gastric acid and ferroportin transports iron across the basolateral membrane into the plasma. Untreated C282Y homozygotes have inappropriate up-regulation of DMT1 and ferroportin mRNA expression in proportion to their serum ferritin level.⁸⁴ Absorption of heme iron is also increased in proportion to serum ferritin levels.^{5, 60} The interaction of transferrin, transferrin receptor, and HFE protein at the basolateral membranes of duodenal absorption cells may play a minor role in regulating iron absorption in persons with HFE hemochromatosis.⁸⁵ SLC40A1 mutations that encode ferroportin that either is not presented normally to the cell surface or has defective iron export activity are associated with loss-of-function, normal or low transferrin saturation, and predominance of iron retention in macrophages. Such mutations decrease iron absorption from the intestine and inhibit iron export from macrophages.

The complicated interactions of HFE, DMT1, transferrin, transferrin receptors, hemojuvelin, hepcidin, and ferroportin in regulating iron absorption in normal individuals and in persons with hemochromatosis are a topic of intense and productive research.^{75, 80, 86, 87, 88, 89, 90}

ORGAN AND CELLULAR INJURY DUE TO IRON OVERLOAD

After many years of increased iron absorption, hepatocyte and Kupffer cell iron storage sites become overloaded and iron accumulates progressively in the myocardium, pancreas, anterior pituitary, spleen, and other organs. Cardiac myocytes, beta-cells of the pancreatic islets, and gonadotroph cells of the anterior pituitary have especially great affinity for otherwise unbound iron. Some individuals with severe iron overload due to hemochromatosis have body iron burdens that are more than 10 times normal. Usually, such individuals do not develop symptoms or signs of illness until after they have had iron overload for three to five decades. Exceptions include the organ damage and death that can occur before the age of 30 years in persons with severe iron overload due to juvenile hemochromatosis.

Iron that is bound to transferrin or stored in modest amounts in ferritin is not toxic. In the presence of excessive iron stores, non-transferrin-bound or non-ferritin iron occurs and generates reactive oxygen species (oxyradicals), especially the hydroxyl radical.^{91, 92, 93, 94, 95, 96, 97} It is likely that hydroxyl, alkoxyl, and peroxy radicals are involved in lipid peroxidation which damages microsomes, mitochondria, and lysosomes. Hydroxyl radicals are also thought to be involved in iron-related damage of enzymes, proteins, nucleic acids, and polysaccharides. Lipid peroxidation then results in disruption of membrane-dependent functions of lysosomes, mitochondria, endoplasmic reticulum, cell membranes, and DNA.^{91, 94} Excess iron and iron-induced oxyradicals may also activate stellate cell transformation to fibroblasts in the liver and act as carcinogens in hepatocytes or extrahepatic parenchymal cells.

DIFFERENTIAL DIAGNOSIS OF IRON OVERLOAD

Many heritable or acquired disorders are associated with increased body iron stores. Some of these disorders appear in Table 25.1,^{1, 12, 13, 20, 21, 22, 23, 24, 26, 27, 36, 72, 73, 74, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200,} including gene location, mode of heritability, and gene mutation responsible for the disorder. Table 25.1 provides guidance for physicians who are evaluating and managing patients with iron overload.

HFE HEMOCHROMATOSIS GENE

HFE Location

The HFE gene is located approximately 4 megabases telomeric to the HLA region on the short arm of chromosome 6(6p). HFE is structurally similar to other HLA class I-like genes. HFE is composed of seven exons, of which the first six encode for the six domains of the HFE protein. The seven exons of HFE result in formation of a messenger RNA transcript of 4.2 kilobases. This in turn results in the synthesis of the HFE product, a protein of 343 amino acids. The most common mutation of HFE (C282Y) associated with iron overload is caused by a mutation of one nucleotide base 845G→A in exon 4 of the HFE gene.³⁶

HFE Mutations

More than 60 mutations of the HFE gene have been reported.^{15, 36, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239} The most common mutation that occurs in people who have hemochromatosis is a change in nucleotide 845 from the normal guanidine to adenine in exon 4 of the HFE gene (referred to as 845G→A). This nucleotide change results in the substitution of tyrosine in place of the normal cysteine in amino acid position 282, referred to as Cysteine282Tyrosine, Cys282Tyr, or C282Y. This mutation causes the majority of iron accumulation in subjects who have hemochromatosis.³⁶

P.665

TABLE 25.1 HERITABLE AND ACQUIRED DISORDERS ASSOCIATED WITH IRON OVERLOAD: DIFFERENTIAL DIAGNOSIS

Heritable Disorder	Chromosomal Assignment	Heritability	Cause of Iron Loading	References
<i>HFE</i> Hemochromatosis	6p21.3	Autosomal recessive	Mutations of <i>HFE</i>	36

Juvenile Hemochromatosis

<i>HJV</i> Hemochromatosis	1q21	Autosomal recessive	Mutations of hemojuvelin	1, 12, 98, 99, 100, 101
<i>HAMP</i> Hemochromatosis	19q13	Autosomal recessive	Hepcidin antimicrobial peptide gene mutations	13, 72, 73, 74
<i>TFR2</i> Hemochromatosis	7q22	Autosomal recessive	Inactivation of transferrin receptor 2	20, 21, 22, 23, 24, 26, 102
<i>SLC40A1</i> Hemochromatosis	2q32	Autosomal dominant	Ferroportin gene mutations	27, 101, 103, 104, 105, 106, 107

Aceruloplasminemia	3q23-q24	Autosomal recessive	Ceruloplasmin gene mutations	147, 148, 149, 150, 151, 152, 153, 154
Hereditary hyperferritinemia and cataract syndrome	19q13.1-q13.3.3	Autosomal dominant	L-Ferritin gene mutations	155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165
Friedreich ataxia	9p23-p11,9q13	Autosomal recessive	Frataxin gene mutations	166, 167, 168, 169, 170, 171, 172, 173
Panthonase kinase-associated neurodegeneration	20p13-p12.3	Autosomal recessive	Panthonase kinase gene mutations	174, 175
β -Thalassemia major	11p15.5	Autosomal recessive	β -Globin gene mutations, chronic hemolysis, red cell transfusions	—
Other chronic hemolytic anemias				
Hereditary X-linked sideroblastic anemia	Xp11.21	X-Linked	δ -Aminolevulinic acid synthase gene mutations	176, 177, 178
X-Linked sideroblastic	Xq13.1-q13.3	X-Linked	ABCB7 mutations ^a	179, 180, 181, 182

anemia with ataxia				
MLASA syndrome ^b	12q24.33	Autosomal recessive	Pseudouridine synthase-1 mutations	183, 184
<i>GLRX5</i> sideroblastic anemia	14q32.13	Autosomal recessive	Glutaredoxin 5 mutations	185, 186
<i>DMT1</i> iron overload ^c	12q13	Autosomal recessive	<i>SLC11A2</i> mutations ^d	187, 188
Pyruvate kinase deficiency	1q21	Autosomal recessive	Pyruvate kinase gene mutations	189, 190, 191
G6PD deficiency ^e	Xq28	X-Linked	G6PD gene mutations	192, 193
Congenital dyserythropoietic anemias				
Type I	15q15.1-q15.3	Autosomal recessive	Ineffective erythropoiesis	194, 195
Type II	20q11.2	Autosomal recessive	Ineffective erythropoiesis	196, 197, 198
Type III	15q21	Autosomal dominant	Ineffective erythropoiesis	199, 200

Acquired Disorder Cause of Iron Loading

Transfusions	Red cell iron infusion
Medicinal iron	Excessive iron ingestion
Iron injections	Parenteral injection
Myelodysplasia with ring sideroblasts	Excessive iron absorption; transfusion
Portacaval shunt	Excessive iron absorption
Hemodialysis	Iron infusion
Nonalcoholic fatty liver disease	Excessive iron absorption

^a ABCB7, ATP-binding cassette, subfamily B, member 7.

^b MLASA, myopathy with lactic acidosis and sideroblastic anemia.

^c *DMT1*, divalent metal transporter-1.

^d *SLC11A2*, solute carrier family 11, member 2.

^e G6PD, glucose-6-phosphate dehydrogenase.

P.666

The second most common HFE gene mutation in hemochromatosis patients is a change in nucleotide 187 from the normal cytidine to guanidine 187C→G in exon 2. This results in substitution of aspartate for the normal histidine at amino acid position 63. Both the C282Y and H63D mutations were identified in the initial report of the isolation and cloning of HFE.³⁶

Of the reported mutations of the HFE gene, 31 are missense mutations that result in substitution of the normal amino acid by another. There are 27 reported nonsense mutations of HFE, 12 of which are splice errors that are associated with intron sequence variants. Eight mutations involve a nucleotide change that does not result in an amino acid substitution (synonymous mutations). Some important HFE gene mutations are given in Table 25.2. Other mutations occur in noncoding regions of HFE.²⁴⁰ It is expected that other rare mutations of the HFE gene will be identified in adults with hemochromatosis phenotypes.

HFE Mutations in Hemochromatosis Patients and in Different Populations

In the first report of the HFE gene and its mutations, 83% of subjects with hemochromatosis were C282Y homozygotes.³⁶ The prevalence of homozygosity for C282Y varies from 33% to 100% among groups of hemochromatosis patients. In the United States, 59% to 89% of hemochromatosis patients are C282Y homozygotes. The percentage of hemochromatosis patients from 14 countries who have the C282Y and H63D genotypes is presented in Table 25.3.^{36 98 228 241 242 243 244 245}

The prevalence of HFE mutations is high in some populations, such as those of Central, Western, and Northern Europe, and in countries that were populated predominantly by people who originated in these areas of Europe, including the United States, Canada, and Australia.^{241, 277} It is predicted that the prevalence of HFE mutations is very low in parts of the world with little or no ancestry from Central and Western Europe, including sub-Saharan Africa (Native Africans), the Middle East, the Orient, and Native Americans in North, Central, and South America. The frequency of homozygosity for the HFE C282Y mutation in the United States varies from 0% to 1.00% in whites, 0% to 0.22% in Mexican Americans, and 0% to 0.06% in blacks (Table 25.4). The prevalence of C282Y, H63D, and wild-type HFE genotypes from nine studies in the United States is presented in Table 25.4.^{211, 242, 244, 278, 279, 280, 281, 282, 283} Extensive data about genotype frequencies in many countries, and from different regions within countries, have been published.^{241, 277, 284}

Hemochromatosis and Iron Overload Screening Study

The largest study of the prevalence of HFE mutations and of serum iron tests was recently completed and published. It is called the HEIRS Study (Hemochromatosis and Iron Overload Screening Study).^{136, 285, 286, 287, 288, 289} Tests for the C282Y and H63D mutations of HFE, serum iron concentration, transferrin saturation, and serum ferritin concentration were measured in about 102,000 outpatients in the United States and Canada. Participants were recalled for additional evaluation if they were C282Y homozygotes or if they had elevated results of transferrin saturation (percent

saturation >50% in men, >45% in women) or elevated serum ferritin (>300 µg/L in men, >200 µg/L in women).

Prevalence rates were derived with Hardy-Weinberg proportions within the five ethnic groups who were not C282Y homozygotes.

“Data from participants with complete information on *HFE* C282Y and H63D mutations, transferrin saturation, and serum ferritin levels, except 1,457 who heard about the study from a participating family member, were included.

Modified from Adams PC, Reboussin DM, Barton JC, et al. Hemochromatosis and iron-overload screening in a racially diverse population. *N Engl J Med* 2005;352:1769-1778.²⁸⁷

Used with permission.

The Study centers were Washington DC; Birmingham, Alabama; Irvine, California; Portland, Oregon; Honolulu, Hawaii; and London, Ontario, Canada. Of 99,711 study subjects, 44,082 were Caucasians, 27,124 were blacks, 12,772 were Asians, 12,459 were Hispanics, 698 were Pacific Islanders, and 648 were Native Americans. The prevalence of C282Y homozygosity was highest in Caucasians (0.44%, 4.4 per 1,000) and lowest in Asians (0.39 per 1,000,000), followed by Pacific Islanders (0.012%), blacks (0.014%), Hispanics (0.027%), and Native Americans (0.11%). The prevalence of the C282Y/C282Y, C282Y/H63D, and H63D/H63D genotypes in the study participants is presented in Table 25.5.²⁸⁷ Among Caucasians, the H63D/H63D and the C282Y/H63D genotypes were about 4 times and 3.5 times as common, respectively, as the C282Y/C282Y genotype.²⁸⁷

Prevalence of HFE Mutations in Other Large Population Studies

In a study of 65,238 Norwegians, 0.68% were C282Y homozygotes.²⁹⁰ In a study of 41,038 participants in a Southern California health appraisal clinic, the prevalence of C282Y homozygosity among 30,418 whites was 0.46% (139 homozygotes).²⁷⁸

Association of Iron Loading and HFE Mutations

Some mutations are associated with severe iron loading, such as C282Y, R330M, IVS3 (+1) G→T, E168X, C282S, R74X, and G93fs (Table 25.2). Some mutations are believed to have a modest or moderate effect on iron accumulation, for example, H63D, S65C, G93R, I105T, and E168Q. Other HFE mutations have been identified in individuals without iron overload or in whom the effect of the mutation on iron accumulation could not be determined, such as V53M, V59M, Q127H, E277K, and in several intron sequence variants. Some mutations code for the normal amino acid (synonymous mutations) and do not affect iron absorption. The HFE mutations with severe, mild, or unknown effects on iron accumulation are shown in Table 25.2.

Interaction of Mutations of Hfe and of Other Genes

Interaction of Mutations of HFE and Hcpidin

Mutations of HFE and other genes involved in maintaining iron homeostasis can have a synergistic effect on iron accumulation in hemochromatosis. A striking example of this is the heavy iron loading that occurred in an individual who had C282Y homozygosity and a mutation of the hepcidin gene (a HAMP mutation resulting in deletion of four nucleotides and methionine50deletion, an intron sequence variant in exon 2 and intron 1, referred to as M50del IVS2+1(-G), a

frameshift deletion). This represents a “digenic” configuration of a mutation in each of two autosomal recessive genes, neither of which alone would likely cause heavy iron accumulation. This digenic genotype caused massive iron overload by age 27 years.²⁹¹ The affected man underwent removal of 27 g of iron for 4 years before his serum ferritin concentration became normal (at diagnosis 1,645 µg/L, after treatment 40 µg/L). Mutations of other genes, such as the transferrin receptor-2 or ferroportin, can also result in heavy iron accumulation in individuals who also have HFE mutations.

Some investigators reported that a variant in the D-loop of mitochondrial DNA (mtDNA) where a T→C substitution occurred at nucleotide 16189 (mtDNA 16189T→C) was associated with more severe iron phenotypes in patients with hemochromatosis.²⁹² Other investigators did not confirm this report.²⁹³ It seems likely that additional mutations in diverse genes will be found to explain increased or decreased rates of iron absorption in C282Y homozygotes.

P.670

FREQUENCY OF HEMOCHROMATOSIS IN MEN AND WOMEN

Hemochromatosis is transmitted as an autosomal recessive condition and therefore there should be equal numbers of male and female homozygotes. Overt iron overload, organ injury, and illness occur more frequently in men than in women with this disorder. Men with hemochromatosis have approximately two and a half times as much mobilizable body storage iron as women. Most women are protected from severe iron overload by the menstrual loss of 15 to 25 mg of iron each month and by the transfer of approximately 750 mg of iron to the fetus during pregnancy. Regardless, menstrual blood losses and pregnancy do not explain all of the differences in body iron stores between male and female homozygotes. Testosterone suppresses hepcidin production²⁹⁴ and this could account in part for the tendency of men with hemochromatosis to develop more severe iron overload than women.

CLINICAL FEATURES OF HEMOCHROMATOSIS

Symptoms

The presence or absence of symptoms in persons with hemochromatosis is related to the stage at which the diagnosis is established. Individuals diagnosed to have hemochromatosis during a routine office visit are expected to have no organ injury and many of them are not heavily iron loaded, if at all. This is common among women, young men, children, and the healthy siblings who undergo family screening after a proband is diagnosed. Subjects in whom the diagnosis is established after they seek medical attention due to symptoms are typically ill (Table 25.6).^{245, 295, 296, 297, 298, 299, 300, 301, 302} These persons usually have iron overload and evidence of organ injury. The frequency of symptoms, physical signs, and laboratory abnormalities in subjects with hemochromatosis (sick probands)

P.671

compared with probands who were identified during screening and compared with their homozygous relatives who were identified during family evaluation (clinically unselected homozygotes) are given in Table 25.7.³⁰³ Approximately 90% to 98% of people who are found to have hemochromatosis during screening are asymptomatic.

The most common symptom in nonscreening hemochromatosis patients at diagnosis is arthralgias, (approximately 40% of homozygotes).²⁴⁵ The joints most commonly involved with typical hemochromatosis arthropathy are metacarpal-phalangeal (MCP) joints, especially the second and third.³⁰⁴ Pain or other manifestations can also occur in knees, hips, shoulders, and other diarthrodial joints. Weakness, fatigue, and lethargy are common but nonspecific symptoms. Weight loss, abdominal pain, loss of libido in men, and palpitations also occur in some iron-loaded homozygotes. The prevalences of arthralgias, abdominal pain, loss of libido or impotence, and palpitations in different study populations are displayed in Tables 25.6 and 25.7.

Physical Examination Abnormalities

Gray or bronze pigmentation is the most common physical examination abnormality in hemochromatosis homozygotes diagnosed in nonscreening settings (35% to 84%). Other common findings include arthropathy (13% to 68%), hepatomegaly (54% to 93%), splenomegaly (10% to 55%), irregular heartbeat, congestive heart failure, telangiectases, and loss of midline body hair or testicular atrophy. The frequency of physical abnormalities in hemochromatosis from nine studies is shown in Table 25.6. The prevalence of self-reported illness according to HFE genotype in two very large US and US-Canadian population screening studies is given in Tables 25.8³⁰¹ and 25.9.²⁷⁸

Laboratory Abnormalities

The most common laboratory abnormalities in subjects with hemochromatosis are elevations of serum iron concentration, percent transferrin saturation, and serum ferritin concentration.^{136, 305} Transferrin saturation may be elevated in children or teenage homozygotes before serum ferritin elevation occurs, long before symptoms or physical examination abnormalities develop. This is attributed to the increased release of iron by macrophages via ferroportin in the presence of low hepcidin levels. The typical values of transferrin saturation according to the method of ascertainment

in 291 Utah homozygous probands are presented in Table 25.10.²⁴⁵ The results of transferrin saturation and serum ferritin concentration in normal individuals, C282Y heterozygotes, C282Y/H63D compound heterozygotes, and H63D homozygotes according to HFE genotype from a large US population screening study are shown in Table 25.11.²⁷⁸

In untreated C282Y homozygotes, the average hemoglobin concentration is greater than that of control subjects without common HFE mutations.^{306, 307} Likewise, the value of mean corpuscular volume of untreated C282Y homozygotes is elevated, sometimes above the upper reference limit, even in patients without liver disease.³⁰⁶ The mean red blood cell count and mean coefficient of variation of mean corpuscular volume (RDW) are lower in C282Y homozygotes.³⁰⁸ These erythrocyte-associated characteristics, usually more pronounced in men than women, are due to the ample amounts of iron constantly available to marrow erythroblasts via transferrin, the saturation of which is increased in most C282Y homozygotes. Genome-wide linkage analyses confirm that a locus (loci) on chromosome 6p21 is significantly associated with hemoglobin concentration.³⁰⁹ This locus is presumed to be HFE.

Radiographs of hands are often abnormal in homozygotes who have arthralgias. Approximately 50% of homozygotes have radiographic changes. The plain films reveal narrowing of the MCP joint spaces, subperiosteal bone resorption, and periarticular demineralization. Plain films of knees may reveal chondrocalcinosis, linear calcium deposition in the cartilage that is visible across the joint space.

The next most common laboratory abnormality in untreated hemochromatosis patients diagnosed in nonscreening venues is elevation of serum levels of alanine aminotransferase and aspartate aminotransferase (8% to 92%). The prevalence of this abnormality varies markedly according to the method of ascertainment (Tables 25.6 and 25.7). Usually, these enzyme levels are elevated two to five times the upper limit of normal in nonscreening subjects. The significance of elevated serum levels of hepatic transaminases is often different in C282Y homozygotes detected in screening programs than in nonscreening patients. In HEIRS Study participants with hyperferritinemia, mean serum levels of transaminase activities were significantly lower in C282Y homozygotes than nonhomozygotes. The probability of being a C282Y homozygote increased as the transaminase activities decreased. Thus, study participants with hyperferritinemia detected in screening are more likely to be C282Y homozygotes if they have normal liver transaminase activities.³¹⁰ If hepatic failure is present, serum transaminase

P.672

and bilirubin levels may be very elevated. Other common laboratory abnormalities include elevation of serum glucose concentration (0% to 82%); arrhythmia on electrocardiography; cardiomegaly on chest radiography; decreased ejection fraction on echocardiography; elevated or very low thyroid-stimulating hormone in hypothyroidism or hyperthyroidism, respectively; and blood test evidence of hypogonadism, usually the hypogonadotrophic type with decreased serum concentrations of testosterone, dihydrotestosterone, luteinizing hormone, and follicle-stimulating hormone.³¹¹ Tables 25.6 and 25.7 show the frequency of lab abnormalities in individuals who have hemochromatosis.

Liver Biopsy Findings

Liver morphology by microscopy is usually normal in homozygotes whose serum ferritin is not elevated. When serum ferritin concentration is elevated, the hepatic parenchymal cell stainable iron is usually increased. The same comments apply to the measured hepatic iron concentration. Many 40- to 50-year-old male homozygotes have hepatic fibrosis when hemochromatosis is diagnosed (2% to 32%) (Table 25.12).²⁴⁵ A range of 0% to 92% of male homozygotes have cirrhosis at the time of diagnosis, usually the sick individuals (Tables 25.6 and 25.7). Most women with hemochromatosis do not have fibrosis or cirrhosis at diagnosis. Cirrhosis is not expected to occur until the hepatic iron concentration is elevated to approximately 22,000 µg (22 mg) of iron per gram of liver dry weight (normal, approximately 1,000 µg iron per gram dry weight).³¹² Hemochromatosis homozygotes who are only identified because they participated in screening studies rarely have heavy liver iron overload or hepatic fibrosis (Tables 25.7 and 25.12).^{245, 285, 303}

In hemochromatosis patients, an elevated serum concentration of collagen type IV correlates strongly (*p* < 0.0001) with hepatic fibrosis or cirrhosis.³¹³ Serum collagen type IV levels in a group of 42 hemochromatosis patients were compared to those of 19 control subjects. A serum concentration of collagen type IV >115 ng/ml had a sensitivity of 100% and a specificity of 69% for far-advanced hepatic fibrosis (grade 3) and cirrhosis (grade 4).³¹³ Among homozygotes who are diagnosed very late, 10% to 29% of those with cirrhosis develop hepatocellular carcinoma.^{314, 315, 316, 317} Hepatocellular carcinoma in hemochromatosis may be multifocal rather than focal and may not cause marked elevation of α-fetoprotein that is common in individuals who have a large nodular hepatoma. Multifocal hepatocellular carcinoma may not be visible by ultrasonography until the diameter of the nodules reaches 1 cm. The frequency of hepatic fibrosis, cirrhosis, and hepatocellular carcinoma in hemochromatosis patients is presented in Tables 25.6, 25.7, and 25.12.

HFE MUTATIONS AND OTHER CONDITIONS

Arthropathy

Arthropathy is common in patients diagnosed to have hemochromatosis in nonscreening settings and is a major cause of morbidity in some individuals.^{18, 21, 22, 23, 24} The proportion of nonscreening patients who have severe iron overload is relatively high and the prevalence of hemochromatosis arthropathy is significantly greater in patients whose serum ferritin levels are greater than 1,000 μg/L at diagnosis than in those with lower serum ferritin levels.^{20, 26} Hemochromatosis homozygotes with arthropathy usually experience symmetrical arthralgias in the second and third MCP and proximal interphalangeal (PIP) joints.³¹⁸ MCP joint swelling, decreased range of motion, and decreased ability to make a fist are typical physical findings. Radiographic findings include hypertrophy and related abnormalities of MCP and PIP joints, subchondral cysts with sclerotic margins at the metacarpal heads, and joint space narrowing, usually with asymmetric cartilage loss. Other degenerative changes that occur in some cases include chondrocalcinosis, involvement of radiocarpal joints, osteophytes at severely affected MCP joints, and generalized osteoporosis of affected hands.^{2, 319, 320} Approximately two-thirds of patients with hand arthropathy have or will develop hip or knee arthropathy. Knee radiographs often reveal chondrocalcinosis.³²⁰ Many patients with hip or knee arthropathy eventually require joint replacement. Other diarthrodial joints are affected less frequently (e.g., shoulders, elbows, ankles, and toes).

TABLE 25.12 LIVER BIOPSY FINDINGS IN SICK, SCREENING, AND CLINICALLY UNSELECTED HOMOZYGOUS RELATIVES: UTAH STUDY OF 505 HOMOZYGOTES

In persons diagnosed to have hemochromatosis in screening programs, the proportion who have severe iron overload is relatively low and thus typical hemochromatosis arthropathy is not common. Among the 98,529 participants in the HEIRS screening study (36,474 men and 62,055 women), there was no significant difference in the incidence of self-reported arthritis between groups of C282Y homozygotes and participants without HFE mutations.²⁸⁷ In another large questionnaire study, there was no significant difference in the prevalence of arthropathy between 45 C282Y homozygotes who were identified by screening and 9,299 control subjects.²⁷⁸ The results of another screening study were similar.³²¹

P.675

The prevalence of common HFE mutations did not differ significantly in 1,000 patients who had inflammatory arthritis and in 1,000 normal control subjects.³²² In another study of patients without a diagnosis of hemochromatosis, the prevalence of HFE C282Y was greater in those with radiographic evidence of hand osteoarthritis than in control subjects. Serum ferritin levels were similar in patients with and without hand osteoarthritis.⁴¹ Some HFE C282Y homozygotes develop rheumatoid-factor-positive rheumatoid arthritis,³²³ psoriatic arthritis, gouty arthritis, or other types of arthropathy not attributable to iron overload. Osteoporosis defined by decreased bone mineral density was present in 34% of 38 C282Y homozygotes and C282Y/H63D compound heterozygotes who had not undergone iron depletion therapy. Osteopenia was present in 79%. Vitamin D and parathyroid hormone values were normal. Hypogonadism was present in 13%.³²⁴

Diabetes Mellitus

Diabetes was reported in early accounts of hemochromatosis^{32, 33, 34} and for years was considered to be essential for establishing a diagnosis of hemochromatosis. Diabetes remains common in patients with hemochromatosis who have severe iron overload and cirrhosis (Tables 25.6 and 25.7).^{299, 300, 315, 325} Siderosis of pancreatic islets, pancreatic fibrosis, and cirrhosis contribute significantly to diabetes pathogenesis in such cases but other factors also influence diabetes risk and expression. Some hemochromatosis homozygotes who have diabetes have elevated body mass index and decreased insulin secretory capacity.^{326, 327} Similar abnormalities occur in mouse models of hemochromatosis.³²⁸ Cirrhosis contributes to insulin resistance and hyperglucagonemia. A family history of diabetes in first-degree relatives is a significant predictor of diabetes risk among persons with hemochromatosis,^{329, 330} consistent with observations that diabetes and hemochromatosis segregate independently as genetic traits.³⁹ Diabetes is associated with decreased survival after diagnosis in nonscreening patients with hemochromatosis and C282Y homozygosity.³³¹

As hemochromatosis case definition has changed from that of a rare, severe iron overload phenotype to a relatively common disorder defined primarily by HFE C282Y homozygosity, the prevalence of diabetes in hemochromatosis case series has decreased to a level that approaches that of the general age- and sex-matched population.³³² Among the 98,529 participants in the HEIRS Study (36,474 men and 62,055 women), there was no significant difference in the prevalence of self-reported diabetes between groups of C282Y homozygotes and the participants with normal HFE genotypes.²⁸⁷ In a study of 22,347 control subjects without HFE mutations, 8.4% reported having diabetes, whereas 5.6% of 124 C282Y homozygotes reported having diabetes. Similarly, 7.0% of C282Y/H63D compound heterozygotes had diabetes.²⁷⁸ The prevalence of HFE C282Y in groups of patients with diabetes is similar to that in corresponding control subjects.^{278, 333, 334, 335, 336, 337, 338}

Other Endocrinopathy

Hypogonadism, thyroid disease, and adrenal insufficiency occur in some hemochromatosis patients, usually those who have been heavily iron loaded for decades. Of nondiabetes endocrinopathy in hemochromatosis, the second most common type is hypogonadism (Tables 25.6 and 25.7). This is usually of the hypogonadotrophic type.^{311, 339} Iron is deposited selectively in the gonadotroph cells of the anterior pituitary.^{295, 311, 339, 340, 341, 342, 343, 344, 345, 346, 347} In a group of 141 ironloaded hemochromatosis patients, 9 patients (6%) had abnormally low testosterone levels. Of these nine patients, eight (89%) also had low values of luteinizing hormone and follicle-stimulating hormone. These findings are characteristic of hypogonadotrophic hypogonadism.³¹¹ Hypothalamic dysfunction occurs in some patients.^{119, 311, 339, 344, 348, 349, 350, 351, 352, 353} Other patients with hemochromatosis have primary gonadal failure typically unrelated to iron overload. In a different study of 181 unrelated men who were HFE C282Y homozygotes, none had hypogonadism.³⁵⁴ It seems reasonable to evaluate for hemochromatosis in individuals who have hypopituitarism of unknown cause.³⁵⁵

In the HEIRS Study, hypothyroidism was detected in 1.7% of 176 HFE C282Y homozygotes and 1.3% of 312 control subjects who did not have C282Y. None of the C282Y homozygotes and 1% of the controls had hyperthyroidism. These minor differences in prevalence were not statistically significant.³⁵⁶

Polycystic ovary syndrome (PCOS) affects approximately 5% of white women and is often associated with decreased serum hepcidin concentration. Homozygosity for the HFE C282Y mutation also is associated with decreased serum hepcidin. In a study of 107 unrelated women who were C282Y homozygotes, a 13-year-old and a 16-year-old had PCOS. Each had elevated serum ferritin concentration and grade 3 to 4 hepatic parenchymal stainable iron.³⁵⁴ It seems likely that low serum hepcidin concentration due to both PCOS with loss of menses at a very young age and HFE hemochromatosis contributed to early-onset iron overload.

Hepatocellular Carcinoma

The relative risk of hepatocellular carcinoma in patients with hemochromatosis who have cirrhosis is 219-fold higher than in patients with hemochromatosis who do not have cirrhosis.^{315, 357} Among patients who have both end-stage hemochromatosis and cirrhosis, 10% to 29% develop hepatoma.^{314, 315, 316, 317, 358, 359} About 3% to 4% of patients with hemochromatosis complicated by cirrhosis develop hepatocellular carcinoma per year.^{357, 360} There are also reports of hepatoma in hemochromatosis patients who did not have cirrhosis.^{361, 362, 363, 364, 365, 366} The histology of primary liver cancer in hemochromatosis is heterogeneous. Although the majority of primary liver cancers in hemochromatosis are of the hepatocellular type, biliary cancers also occur, including cholangiocarcinoma and combined hepatocellular cholangiocarcinoma.^{317, 366}

In some reports, the proportion of patients with hepatocellular carcinoma who also have C282Y homozygosity^{367, 368} or C282Y heterozygosity is significantly increased.^{368, 369, 370} In another report, the prevalence of HFE mutations in patients with hepatocellular carcinoma was similar to that in control subjects.³⁷¹ Positive associations of HFE mutations, chronic viral hepatitis, and hepatocellular carcinoma have been reported.^{367, 370} Recent guidelines have been published about the evaluation and management of patients who have hepatocellular carcinoma.^{372, 373, 374}

Colorectal Polyps and Colorectal Cancer

In the Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial, a study of 679 persons with advanced distal adenoma and 697 control persons revealed no significant relationship of C282Y and H63D or dietary iron intake on the risk of advanced distal adenomatous colorectal polyps.³⁷⁵ In a study of 475 case patients and 833 control subjects, C282Y and H63D mutations were associated with an increased risk of colon cancer.³⁷⁶ In a cohort study of 28,509 participants, C282Y homozygotes had twofold increased risk for colorectal cancer and female C282Y homozygotes were at twofold increased risk for breast cancer.³⁷⁷

Other Types of Cancer

Iron can be carcinogenic. Possible mechanisms of carcinogenesis include redox cycling of iron, that produces reactive oxygen species and free radicals, which in turn cause lipid peroxidation and damage to proteins and DNA.³⁷⁸ Iron may facilitate tumor cell growth and modify immune system responses.³⁷⁹ The results of some studies suggested that HFE mutations were associated with

P.676

colorectal or breast or other carcinomas,^{377, 380, 381, 382} whereas results of some studies did not identify HFE mutations as a risk factor for cancer.^{383, 384, 385, 386} In the cohort study of 28,509 participants cited above, male C282Y homozygotes did not have increased risk for prostate cancer.³⁷⁷ C282Y/H63D compound heterozygotes and C282Y heterozygotes did not have increased risk for colorectal, breast, prostate, or other cancers.³⁷⁷ In a meta-analysis of the risk of 66,263 people with HFE mutations to develop 31 different disorders, compared with 226,515 control subjects without HFE mutations, there was no identifiable risk for the development of cancers other than hepatocellular carcinoma.³⁸⁴

Porphyria Cutanea Tarda

The most common type of porphyria is sporadic porphyria cutanea tarda. An elevated amount of storage iron is characteristic of this disorder. The interaction of iron and porphyria cutanea tarda has been reviewed.^{112, 387, 388, 389} In addition, the presence of one or two HFE C282Y or H63D mutations is common in subjects with sporadic porphyria cutanea tarda and increased storage iron. Some patients with porphyria cutanea tarda (either sporadic or familial) and heavy iron loading are homozygous for HFE mutations.^{109, 111, 390, 391, 392, 393}

Porphyria cutanea tarda occurs in individuals who have decreased activity of uroporphyrinogen decarboxylase which results in the accumulation of uroporphyrinogen I. In the presence of excess iron, accumulated uroporphyrinogen undergoes iron-mediated oxidation, resulting in production of uroporphomethene. Uroporphomethene then further inhibits the already decreased activity of uroporphyrinogen decarboxylase.^{394, 395} An association of the uroporphyrinogen

decarboxylase gene on chromosome 1q and hemochromatosis alleles on chromosome 6p was first reported in 1989.¹⁰⁹ This was substantiated after HFE was cloned and sequenced and HFE mutations were identified.^{111, 112, 396} In a study of 108 subjects in Utah who had porphyria cutanea tarda, 19% were C282Y homozygotes and 7% were C282Y/H63D compound heterozygotes.¹¹¹ The HFE mutation(s) causes increased iron absorption which further depresses the already decreased activity of the enzyme uroporphyrinogen decarboxylase. This results in the accumulation of uroporphyrin I in organs. Deposition of porphyrin in skin causes photosensitivity, blistering, and scarring.

Risk factors for the expression of porphyria cutanea tarda include common HFE mutations,^{396, 397, 398, 399, 400, 401, 402, 403} hepatitis C, alcoholism, oral estrogen therapy (but possibly not transdermal estrogen),^{110, 387, 398} and tamoxifen.³⁹⁷ Hepatitis C infection, a potent risk factor, occurs in 28% to 74% of individuals with porphyria cutanea tarda. A 2002 study from Galveston was performed to assess the factors involved in the expression of porphyria cutanea tarda.³⁹⁹ In 39 consecutive patients with porphyria cutanea tarda, 9% had HFE genotype C282Y/C282Y, 9% had C282Y/wt, 12% had C282Y/H63D, 9% had H63D/H63D, and 26% had H63D/wt. None had the S65C mutation. Among these patients, 79% drank alcohol, 73% of 11 women took estrogens, 86% were smokers, and 74% were positive for the hepatitis C antibody. The authors concluded that HFE mutations were common and that the expression of porphyria cutanea tarda was multifactorial. Three or more risk factors for expression of porphyria cutanea tarda were detected in 92% of the 39 patients.³⁹⁹

The prevalence of the C282Y, H63D, and S65C mutations of HFE and antibody to the hepatitis C virus was compared in 65 patients with sporadic porphyria cutanea tarda and in 108 control subjects.⁴⁰⁰ Of the porphyria patients, 17% had the C282Y mutation (4% of controls). There was no significant difference in the prevalence of the H63D and S65C mutations or compound C282Y/H63D heterozygosity between groups. Hepatitis C antibodies were detected in 28% of the patients with porphyria cutanea tarda. In another study of porphyria cutanea tarda patients in France, hepatitis C was identified as the major risk factor for porphyria.⁴⁰¹

In a study of 190 German patients with sporadic porphyria cutanea tarda and 115 age-matched healthy blood donors, 39% of patients with porphyria had HFE C282Y (3% of control subjects) and 12% were C282Y homozygotes (0% of controls).⁴⁰² The H63D mutation was present in 45% of patients with porphyria (10% of controls) and 9% of patients with porphyria were C282Y/H63D compound heterozygotes. In studies among the Basque population in Spain, patients with porphyria cutanea tarda did not have increased frequency of HFE C282Y, H63D, or S65C mutations. Hepatitis C was present in 35% of the porphyria patients.⁴⁰³

Tamoxifen therapy in patients with breast cancer has been associated with the occurrence of porphyria cutanea tarda.^{397, 404, 405} A woman with porphyria cutanea tarda that was caused by oral contraceptives only experienced full remission of porphyria while undergoing anastrozole therapy for metastatic adenocarcinoma of the breast.⁴⁰⁴

Steatohepatitis

Many reports of the prevalence of HFE gene mutations and/or hyperferritinemia in subjects with nonalcoholic steatohepatitis were reviewed recently.^{406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421} In 36 men in Massachusetts who had nonalcoholic steatohepatitis, 2.8% were C282Y homozygotes, 17.0% were C282Y heterozygotes, 5.6% were H63D homozygotes, and 44.0% were H63D heterozygotes.⁴¹⁹ In 348 control subjects, none was a C282Y homozygote, 11.0% were C282Y heterozygotes, 2.9% were H63D homozygotes, and 26.0% were heterozygous for the H63D mutation. Individuals with nonalcoholic steatohepatitis who had a HFE mutation had higher levels of transferrin saturation and serum ferritin, and those with C282Y had significantly higher levels of alanine aminotransferase and a greater level of hepatic fibrosis than those without C282Y.⁴¹⁹ Insulin resistance syndrome is common in people who have nonalcoholic steatohepatitis, with or without mutations of HFE.^{415, 417, 420, 421, 422}

Hereditary Spherocytosis

Individuals who have hereditary spherocytosis may develop severe iron overload and hepatic cirrhosis if they are HFE C282Y homozygotes or heterozygotes.^{393, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433} Iron overload can also occur in patients with hereditary spherocytosis who do not have common HFE mutations.^{434, 435} In a Utah family, for example, two brothers with C282Y homozygosity had iron overload.⁴²⁴ Iron overload in the propositus with both hemochromatosis and hereditary spherocytosis was much more severe than that of his brother who had hemochromatosis without hereditary spherocytosis. The son of the propositus was a C282Y heterozygote who also had hereditary spherocytosis. His serum ferritin concentration and liver iron stores were modestly elevated.

β-Thalassemia Minor

β -Thalassemia minor and hemochromatosis sometimes occur in the same person. In one family, an index patient with β -thalassemia minor and hemochromatosis had a brother with β -thalassemia minor who was a C282Y homozygote. The proband's wife was also a C282Y homozygote. One of their children had β -thalassemia minor and hemochromatosis, whereas the other had hemochromatosis alone. The proband's brother married a woman who was a C282Y/wt heterozygote. Both of their children were C282Y homozygotes.⁴³⁶ Some persons with β -thalassemia minor who have common HFE mutations develop iron load.^{437, 438, 439, 440, 441, 442} In a study of 22 iron-loaded Italian patients with β -thalassemia minor and 62 relatives, β -thalassemia trait appears to worsen the iron-related complications of C282Y homozygosity. It is believed that the mild ineffective erythropoiesis of

P.677

β -thalassemia trait exaggerates the amount of iron absorbed by the duodenum. C282Y heterozygotes and H63D heterozygotes with β -thalassemia trait did not develop iron overload.⁴³⁷ In some other populations, heterozygosity for common HFE mutations appeared to be unassociated with development of iron overload in persons who also had thalassemia minor.^{443, 444, 445, 446}

On the island of Sardinia, an area not reached by Celtic migrations, HFE C282Y is very rare. The H63D mutation prevalence is similar to that of other populations,²⁷⁷ and the prevalence of β -thalassemia minor is 13%.⁴³⁸ Among 152 Sardinian men who had β -thalassemia minor, approximately 2.6% were H63D homozygotes, 29.5% were H63D/wt heterozygotes, and 68% were wt/wt (normal HFE genotype). Concurrent control subjects were not studied.⁴³⁸

In a study from Turin, 71 subjects with transfusion-dependent β -thalassemia major and 200 control subjects were tested for C282Y and H63D.⁴³⁹ None of the patients (or controls) was a C282Y homozygote. One patient (1.4%) was a C282Y/H63D compound heterozygote (similar to 0% among controls); 21.0% of patients (20.0% of controls) were H63D heterozygotes; and one patient (1.4%) was a H63D homozygote (1.0% in controls). The latter patient had greater iron overload than expected. The authors concluded that H63D homozygosity caused the heavy hepatic iron accumulation and advanced hepatic fibrosis. Individuals with either HFE H63D or C282Y were more heavily iron loaded than could be explained by transfusion-dependent homozygous β -thalassemia alone.

Refractory Anemia with Ringed Sideroblasts

Iron accumulation varies in this myelodysplastic disorder.¹⁵⁸ In 40 patients from Switzerland, Greece, and France who had refractory anemia with ringed sideroblasts and nontransfusion iron overload, 1.25% had C282Y. This prevalence was similar to that in 200 normal control subjects (2.50%). The prevalence of the H63D mutation was also similar in patients and controls (19% and 13%, respectively).⁴⁴⁷ Ineffective erythropoiesis alone may account for the increased intestinal absorption of iron in most nontransfused patients with refractory anemia with ringed sideroblasts.

X-Linked Sideroblastic Anemia

Some men with X-linked sideroblastic anemia (mutations of the aminolevulinic synthase gene, (ALAS2) with ringed sideroblasts and heavy iron overload also have HFE mutations. Coinheritance of X-linked sideroblastic anemia and HFE gene mutations was first described in a 59 year-old French man who had hepatic iron overload and C282Y/H63D compound heterozygosity. His iron overload was much more severe than that of his 61 year-old brother who had X-linked sideroblastic anemia but no HFE mutation.⁴⁴⁸

Among 18 unrelated patients with X-linked sideroblastic anemia, 17.0% had HFE C282Y (5.5% in white controls) and 23.0% had H63D (15.0% in controls).⁴⁴⁹ Prevalence of the C282Y mutation was significantly greater in the patients with sideroblastic anemia than in controls, but prevalence of H63D was similar in both groups. After iron depletion, the responsiveness of anemia to pyridoxine supplementation increased in some patients. Coinheritance of one or more HFE mutations and a mild mutation of ALAS2 can result in heavy iron overload.⁴⁵⁰ The iron status of patients with mutations of ALAS2, with or without HFE mutations, has been reviewed.^{451, 452, 453, 454}

Infections in Hemochromatosis Patients

Individuals who have hemochromatosis, especially those with cirrhosis, are susceptible to infection by organisms that rarely cause illness in people with normal body iron stores, including *Vibrio vulnificus* and *Yersinia enterocolitica*.^{455, 456} ^{457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468} *Listeria*,^{469, 470} *Escherichia coli*,⁴⁷¹ and zygomycosis^{472, 473, 474} may also cause severe and sometimes unusual infections in hemochromatosis patients.

Vibrio vulnificus

V. vulnificus is a motile free-living, Gram-negative bacillus that grows as normal flora in warm coastal saline waters worldwide. It usually does not cause infection in humans except in persons who have iron overload, cirrhosis, compromised immunity, or renal insufficiency. When ingested with raw shellfish (especially oysters), it can cause gastroenteritis, septic arthritis, or fatal septicemia.^{466, 467, 468, 475, 476} Serious wound infections have also occurred in patients with hemochromatosis.⁴⁶⁸ Invasive organisms are encapsulated. The organism thrives in blood that has elevated iron content⁴⁶⁰ but can also derive iron for its own metabolism from erythrocytes or hemoglobin. Most infections in patients with hemochromatosis have been reported from states adjacent to the Gulf of Mexico and from Northern Australia. In both areas, HFE hemochromatosis is common in whites and *V. vulnificus* is abundant in coastal waters.

Yersinia enterocolitica

Y. enterocolitica belongs to the family Enterobacteriaceae. It can cause transfusion-associated sepsis, gastroenteritis, septic arthritis, hepatic abscesses, osteomyelitis, or bloody diarrhea. It is usually ingested in contaminated water, pork, milk, bean sprouts, or chocolate.^{477, 478} Unlike *V. vulnificus*, *Yersinia* is often present in colder climates or occurs as a contaminant in any climate. In patients with hemochromatosis, *Yersinia* can cause severe infections,⁴⁰⁴ including bacteremia⁴⁷⁷ and multiple hepatic abscesses.^{470, 478, 479, 480, 481, 482, 483}

IgG Deficiency

Some patients with hemochromatosis and HFE C282Y homozygosity have frequent, severe, or unusual infections and common variable immunodeficiency or immunoglobulin (Ig) G subclass deficiency.⁴⁸⁴ Approximately 30% of probands have selective IgG isotype deficiency, especially that of subclasses IgG₁ or IgG₃. Deficiency of IgA or IgM is uncommon. Mean values of age, transferrin saturation, and serum ferritin at diagnosis and phlebotomy units required to induce iron depletion were similar in probands with or without CVID or IgGSD; phlebotomy had no effect on IgG levels.⁴⁸⁴ There was concordance of Ig and hemochromatosis phenotypes in probands and respective human leukocyte antigen (HLA)-identical siblings and a significant positive association of selective IgG deficiency to C282Y-bearing chromosome 6p HLA haplotypes that included HLA-A*03, B*07. This suggests that a gene that modulates IgG subclass levels occurs on these hemochromatosis-associated chromosomes.⁴⁸⁴

Coronary Artery Disease

Hemochromatosis can cause cardiac arrhythmias or congestive heart failure due to siderosis of conducting fibers and cardiac myocytes.^{297, 300, 302, 485, 486, 487, 488, 489, 490, 491, 492} This complication is much more prevalent in juvenile hemochromatosis than in HFE hemochromatosis. It was estimated that German adults with hemochromatosis had a 300-fold increased risk of developing cardiomyopathy.³¹⁵ In a more recent Swedish study of nationwide, population-based health and census registers, the risk of cardiomyopathy in persons with hemochromatosis was significantly elevated (hazard ratio 3.2 [95% CI 2.15 to 4.81]), but the risk of ischemic heart disease was barely elevated.⁴⁹³ Neither cardiomyopathy nor ischemic heart disease risk was increased in first-degree relatives of persons with hemochromatosis.⁴⁹³ Most studies have revealed no association between coronary

P.678

artery disease and HFE mutations.^{494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505} Other studies suggest that an association exists.^{506, 507} Total mean serum cholesterol and low-density lipoprotein levels were lower in C282Y homozygotes than in HFE wild-type participants in the HEIRS Study.⁵⁰⁸ Whether these differences influence manifestations of coronary or peripheral atherosclerosis in C282Y homozygotes is unknown.

DIAGNOSIS

History and Physical Examination Findings

Recent guidelines and reviews have been published about screening and about the evaluation and management of individuals in whom hemochromatosis is suspected, and for relatives of a person who has HFE hemochromatosis.^{360, 509, 510, 511, 512, 513} A large percentage of HFE C282Y homozygotes who are identified during screening studies do not have symptoms of illness and do not have persistently elevated serum ferritin concentration.^{136, 278, 287, 514, 515} Currently, screening of the general population for hemochromatosis is not recommended.⁵¹⁶

Hemochromatosis with iron overload may be suspected in an individual who has some combination of the following: arthralgias, right upper quadrant abdominal pain, impotence, palpitations, unexplained fatigue or weight loss, gray-bronze skin, hepatomegaly, stigmata of portal hypertension, diabetes, or hypogonadism. Most hemochromatosis homozygotes do not have these findings. Individuals in whom the diagnosis is established during routine screening are nearly always

asymptomatic and have no physical examination abnormalities. People in whom the diagnosis is established after seeking evaluation due to illness usually have several of the symptoms and physical examination abnormalities stated above. Only heavily iron-loaded patients with far-advanced organ injury have all of the above symptoms and physical examination abnormalities. The wide variation in the frequency of symptoms and signs of hemochromatosis from 12 reports appears in Tables 25.6, Tables 25.7, Tables 25.8 and 25.9.

Laboratory Findings

Transferrin saturation is the first blood test to become elevated in hemochromatosis homozygotes and usually is greater than 60% in symptomatic men and greater than 50% in symptomatic women.^{245, 302, 303, 517} Unbound iron-binding capacity is usually decreased in untreated homozygotes.^{518, 519, 520, 521} In iron-loaded patients, serum ferritin concentration is elevated. Liver stainable iron and the hepatic iron index are also elevated in iron-loaded homozygotes. The sensitivity of elevated transferrin saturation to identify a patient with hemochromatosis is 94% to 98%, and its specificity is 70% to 98%.^{303, 517} Typical results of transferrin saturation and serum ferritin concentration in different groups of hemochromatosis homozygotes are displayed in Tables 25.10 and 25.11. HFE C282Y homozygosity was present in 89% of hemochromatosis patients in the Utah studies, whether or not iron overload was present.²⁴⁵

Evaluation of Relatives

After the diagnosis of hemochromatosis is established in an index patient (proband), it is important to study his or her siblings. Test selection is the same as for the index patient: transferrin saturation; serum ferritin concentration; and HFE mutation analysis to identify C282Y, H63D, and S65C alleles. Young homozygous siblings of a hemochromatosis proband may have a normal serum ferritin concentration.²⁴⁵ Serum ferritin levels should be measured at 2- or 3-year intervals. When serum ferritin becomes elevated, it is reasonable to begin intermittent phlebotomy therapy to prevent accumulation of excess iron in the liver and other organs.

HFE homozygous relatives who have marked elevation of serum ferritin concentration greater than 700 $\mu\text{g/L}$ ⁵²² or greater than 1,000 $\mu\text{g/L}$ ^{523, 524} and elevated serum concentrations of hepatic transaminases may have hepatic cirrhosis. Liver biopsy in such individuals is usually necessary to determine the presence or absence of hepatic fibrosis or cirrhosis and allows measurement of hepatic iron stores. Typical liver biopsy findings in iron-loaded homozygotes appear in Figure 25.1 and Table 25.12. The great majority of homozygous relatives identified during family screening are less iron loaded and have fewer complications than their corresponding probands. Authors of a recent article made recommendations about when and for whom to advise liver biopsy in these settings.⁵²⁵

Heterozygous Relatives

HFE heterozygotes do not become iron loaded unless they have an additional disorder that increases iron accumulation.⁵²⁶ There was no difference in the amount of heme iron or non-heme-iron absorption in C282Y heterozygotes and normal control subjects. Similarly, differences in non-transferrin-bound iron, transferrin saturation, or serum ferritin levels did not differ significantly between C282Y heterozygotes and normal controls.⁵²⁷ Transferrin saturation and serum ferritin concentration measurements in large numbers of C282Y heterozygotes and normal individuals are displayed in Table 25.11.²⁷⁸

Because approximately 10% of whites of Central, Western, and Northern European ancestry are C282Y heterozygotes, the occurrence of hemochromatosis in whites in consecutive generations is common. It seems reasonable to measure transferrin saturation or unbound iron-binding capacity in the interested parents and adult children of homozygotes, in addition to all siblings of the proband.

Homozygous Relatives

In a study of the relatives of 291 hemochromatosis probands, 214 homozygous relatives were identified.²⁴⁵ When these 214 clinically unselected individuals were stratified by age and sex, it became apparent that 90% of the homozygous male relatives were iron loaded by age 40 years, and 52% had iron-related organ injury. Clinically unselected female homozygous relatives became iron loaded on average approximately one decade later

P.679

than men. After age 50, 88% of clinically unselected female homozygous relatives became iron loaded and 16% of them had iron-related organ injury.²⁴⁵ The results of transferrin saturation and serum ferritin concentration tests in 291 probands and their 214 clinically unselected homozygous relatives in the Utah studies are displayed in Table 25.10.

FIGURE 25.1. Grade 4 hepatic parenchymal cell stainable iron in a 30-year-old asymptomatic HFE C282Y homozygous woman who was evaluated after her sick brother was found to have hemochromatosis.

MANAGEMENT

Phlebotomy Therapy

Detailed discussions of phlebotomy therapy for hemochromatosis patients have been published.^{303, 528} Overall, men require approximately twice as many units of phlebotomy to induce iron depletion as women.^{301, 303, 529} Complications of hemochromatosis that respond to and complications that do not improve after phlebotomy therapy are displayed in Table 25.13. Treatment for specific problems usually should be managed as in patients who do not have hemochromatosis.

Initial Weekly Phlebotomy Schedule

The main treatment of iron-loaded hemochromatosis patients is phlebotomy therapy.^{303, 528, 529} In a phlebotomy of 500 ml of whole blood with a hematocrit of 40%, 200 ml of packed red blood cells are removed. Because each 1 ml of packed red cells contains about 1 mg of iron, each 500-ml phlebotomy removes about 200 mg of iron. When the diagnosis of iron overload due to hemochromatosis is established, it is important to start the first phase of phlebotomy therapy. Serum ferritin level, not serum iron or transferrin saturation levels, should be used to monitor levels of storage iron during phlebotomy.⁵³⁰

TABLE 25.13 CLINICAL CHANGES EXPECTED FOLLOWING PHLEBOTOMY THERAPY

Observed Complications of Iron Overload	Expected Treatment Outcome
No complications	Prevention of complications of iron overload; normal life expectancy.
Weakness, fatigue, lethargy	May resolve if only due to iron overload.
Elevated hepatic transaminases in serum	Resolution or marked improvement.

Hepatomegaly	Resolution often occurs.
Hepatic cirrhosis ^a	Usually no change.
Increased risk for primary liver cancer ^b	May persist in presence of cirrhosis.
Right upper quadrant pain ^c	Resolution if only due to iron overload.
Arthropathy	Arthralgias may improve; joint deformity not expected to resolve; worsening sometimes occurs.
Hypogonadotropic hypogonadism	May resolve if pituitary injury is not extensive.
Diabetes mellitus	Occasional improvement, often temporary.
Hyperthyroidism, hypothyroidism	Resolution is rare.
Cardiomyopathy	Resolution sometimes occurs.
Hyperpigmentation	Resolution usually occurs.
Hyperferritinemia ^d	Resolution.
Hyperferremia	Usually decreases, then rises again after cessation of phlebotomies.
Excess absorption and storage of nonferrous metals ^e	Little or no change.
Infection with <i>Vibrio vulnificus</i> or other bacteria	Little or no change.

^a Regression was reported in some patients. Falize L, Guillygomarch A, Perrin M, Laine F, Guyader D, Brissot P, Turlin B, Deugnier Y. *Hepatology* 2006;44:472-477.⁴⁴⁶

^b Increased risk is usually only in those who have hepatic cirrhosis.

^c Right upper quadrant pain that is only due to iron overload usually improves, but not if the pain is due to hepatocellular carcinoma, portal vein thrombosis, gallbladder disease, or other non-iron causes.

^d Serum iron levels may be normal or subnormal in persons with hemochromatosis due to severe iron deficiency, chronic inflammatory or infectious disease, vitamin C deficiency, or prolonged fasting.

^e Cobalt, manganese, zinc, and lead.

Modified from Barton JC, McDonnell SM, Adams PC, et al. Management of hemochromatosis. *Ann Intern Med* 1998;129:935.⁵²⁸ Used with permission of publisher.

Most iron-loaded homozygotes tolerate removal of 500 ml of whole blood each week. Some women, small individuals, or elderly patients may only tolerate removal of 250 ml of whole blood each week. Twice-weekly phlebotomy may be performed for very heavily iron-loaded patients who have cardiac arrhythmias or hepatic failure in an effort to improve cardiac and hepatic function quickly. Phlebotomy therapy should be continued until the hemoglobin drops by approximately 1 to 2 g/dl below baseline, the mean corpuscular volume drops by approximately 3 to 5 fl below baseline, and serum ferritin concentration drops to 20 to 50 µg/L. These findings provide evidence of iron-limited erythropoiesis, which concludes the initial rapid sequence phase of phlebotomy therapy. The patient then enters the second, life-long maintenance phase of phlebotomy therapy.^{303, 528, 529, 530, 531, 532}

Life-long Maintenance Phlebotomy Schedule

After the initial iron depletion is accomplished, the patient enters the life-long maintenance phase of phlebotomy therapy. Removal of 500 ml of whole blood every 2 to 4 months (every 3 to 6 months in women) prevents re-accumulation of

excessive organ storage iron. The goals of life-long maintenance phlebotomy therapy include maintenance of a normal hemoglobin level and maintenance

P.680

of the serum ferritin concentration less than 300 µg/L in men and less than 200 µg/L in women.⁵³³ A very low serum ferritin and the presence of anemia indicate that the frequency of phlebotomy therapy can be decreased to 4- or 6-month intervals.

Patients and physicians often want to estimate the duration of weekly phlebotomy therapy to achieve iron depletion. Based on a study of the correlation of serum ferritin to the number of grams of iron removed by phlebotomy therapy, 1 µg/L of pretreatment serum ferritin corresponded to ~8 mg of mobilizable iron.⁵²² A person whose pretreatment serum ferritin concentration is 600 µg/L is likely to have ~4,800 mg (8×600 mg) of mobilizable storage iron. Each ml of centrifuged red blood contains about 1 mg of iron and each 500-ml unit of blood with a hematocrit of 40% contains approximately 200 mg of iron. Therefore, a patient whose serum ferritin is 600 µg/L is predicted to undergo ~24 units of phlebotomy to achieve iron depletion ($[8 \times 600 \text{ mg}] = 4,800 \text{ mg}/200 \text{ mg/unit} = 24 \text{ units}$). This simple estimate holds reasonably well except in patients whose serum ferritin is elevated out of proportion to storage iron due to hepatic necrosis or another source of inflammation that causes hyperferritinemia. After patients achieve iron depletion by phlebotomy, the number of units of whole blood removed, multiplied by 200 mg iron per phlebotomy, provides a reliable calculation of the number of grams of iron that were removed.

Hemochromatosis Homozygotes as Blood Donors

Experts in the Department of Transfusion Medicine at the National Institutes of Health in Bethesda studied hemochromatosis patients as blood donors for patients treated at the National Institutes of Health.⁵³⁴ They evaluated 1,402 units of blood from hemochromatosis donors and concluded that if such individuals do not have serologic results necessitating deferral, they do not pose a health risk for recipients. The authors also noted that these donors could significantly augment the blood supply at the Institutes. After 27 months of study, blood from hemochromatosis donors represented 14% of all blood donations. In another report, an ethicist at the Centre for Environmental Philosophy and Bioethics of the University of Ghent, Belgium concluded that hemochromatosis patients can be free, voluntary, altruistic blood donors if they do not request any benefit other than blood removal.⁵³⁵ When phlebotomy therapy is performed in a setting other than a blood bank, the blood cannot be collected and processed properly for future transfusion.

Clinical Changes after Iron Depletion

If hepatic cirrhosis and arthropathy were not present before iron depletion therapy, these complications of hemochromatosis may be preventable by initial iron depletion followed by life-long maintenance phlebotomy therapy. An important question is whether hepatic fibrosis or cirrhosis can diminish following iron depletion. Regression of hepatic fibrosis was studied in 36 hemochromatosis patients who underwent two liver biopsies, the first one before and the second after iron depletion, with an interval of at least 2 years between biopsies.⁵³⁶ Regression of fibrosis occurred in 9 of 13 patients whose initial fibrosis was far advanced (grade 3), and in 8 of 23 whose initial biopsy showed cirrhosis (grade 4). The clinical changes that may occur following iron depletion appear in Table 25.13.⁵²⁸

Dietary Recommendations

Persons with hemochromatosis have increased risk to develop a life-threatening infection with *V. vulnificus* from raw shellfish (see the section, "Infections"). It is prudent to advise these individuals not to consume raw shellfish, although consumption of cooked shellfish is safe. Much more iron can be removed in each 500-ml whole blood phlebotomy each week than can be absorbed during that week. For this reason, it is not necessary to impose severe dietary restrictions in an attempt to avoid all foods that contain iron. Regardless, heme iron of meat, especially red meat, is readily absorbed. It is reasonable to advise patients to eat red meat in moderation, to decrease dietary intake of saturated fat and animal protein, and to increase consumption of fresh vegetables and fruit, as for anyone else who follows a prudent cardiovascular diet.⁵²⁸

Alcohol Intake

Alcohol can be hepatotoxic. Individuals with hepatic damage from iron overload may benefit from avoiding drinks containing alcohol. It is estimated that 30 g^{317, 537} or greater than 60 g^{538, 539} of alcohol per day can worsen iron-related liver damage. Consumption of these amounts of alcohol by a person with cirrhosis may also increase the risk of hepatocellular carcinoma.^{317, 538, 539}

Vitamins

It is reasonable to advise hemochromatosis patients to avoid medicinal intake of vitamin C (ascorbic acid) because it can increase the absorption of dietary iron, mobilization of storage iron, or production of free radicals.^{540, 541, 542, 543, 544} Vitamin C also may cause oxidative damage of the myocardium and cardiac conduction system, resulting in rare fatal arrhythmias in ironloaded patients who have hemochromatosis or thalassemia major.^{541, 544, 545, 546, 547} It seems reasonable for hemochromatosis patients to not take multiple vitamins that contain iron.

PROGNOSIS

The outlook for an iron-loaded hemochromatosis patient is related to whether the patient undergoes iron depletion therapy before the development of cirrhosis or diabetes mellitus. In a study of 111 hemochromatosis patients in England, the average survival of 85 people who underwent phlebotomy therapy was 63 months, compared with 18 months in the 26 subjects who did not become iron depleted.³¹⁴ In a study of survival among 251 hemochromatosis patients in Germany, survival of those who became iron depleted was similar to that of the background population.³⁰⁰ Hemochromatosis patients with diabetes had a 10-year survival of 65%; in patients without diabetes, the survival was 90%. The 10-year survival of hemochromatosis patients with cirrhosis was 72%, whereas survival of patients without cirrhosis was 82%. Iron overload that could not be depleted within 18 months from the onset of phlebotomy therapy was also associated with decreased survival. In 422 hemochromatosis probands homozygous for HFE C282Y, serum levels of ferritin greater than 1,000 µg/L at diagnosis were positively associated with male sex and cirrhosis. Even with treatment, the relative risk of death from iron overload was fivefold greater in probands with serum levels of ferritin greater than 1,000 µg/L.⁵⁴⁸ Additional reports of survival and prognosis of hemochromatosis patients have been published.^{299, 325, 549, 550}

IMAGING OF THE LIVER

Computed Tomographic Scanning of the Liver

Single-energy computed tomographic (CT) scanning is not adequately sensitive to distinguish hepatic iron overload from a fatty liver. CT scanning also has very limited value in the assessment of sources of hepatic inhomogeneity, including edema, regenerative nodules, perfusion abnormalities, iron, fibrosis, or cirrhosis.⁵⁵¹ Similarly, density histogram analysis of unenhanced hepatic CT does not distinguish among most diffuse liver diseases.⁵⁵²

P.681

Dual-energy CT scanning is able to distinguish hepatic iron from fat.⁵⁵³ In a dual-energy CT scan, an iron-loaded liver appears brighter than paraspinous muscles.

Magnetic Resonance Imaging of the Liver

Magnetic resonance (MR) imaging has largely replaced CT scanning in the evaluation of livers that are presumed to be cirrhotic. Some of the advantages of MR scanning include superior contrast resolution, multiplanar capability, greater sensitivity and specificity in the detection and characterization of abnormalities, and no use of ionizing radiation.⁵⁵¹ MR imaging can be used to identify hepatic cirrhosis, regenerating nodules, increased iron, and hepatocellular carcinoma in subjects who have hemochromatosis.^{554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564}

Iron is a paramagnetic element that becomes magnetized in a magnetic field. The result is that the transverse (T2) relaxation time of iron becomes shortened compared with the longitudinal (T1) relaxation time. In an iron-loaded liver, the shortened T2 relaxation time causes a decrease in signal intensity. The result is that an iron-loaded liver appears darker than paraspinous muscles on T2-weighted MR images. The proton transverse relaxation rate (R2) is related to the presence of iron. For this reason, the R2 value is expected to allow measurement of a wide range of liver iron concentrations on MRI machines that have a magnetic field strength of 1.5 Tesla.⁵⁵⁵ Comparison of both MR imaging and biomagnetic liver susceptometry in 23 patients yielded a high correlation over a wide range of hepatic iron concentration.⁵⁵⁶

Gradient-echo MR scanning after gadolinium is considered to provide the most useful information about iron stores, using both T1- and T2-weighted images. An MR magnet strength of 1.5 tesla provides better predictive ability than a 0.5-tesla magnet. The intensity of the signal in liver is often compared to signal intensity in paraspinous muscles. Iron causes increased attenuation of the gradient-echo signal in hepatocytes,^{551, 554, 557, 559, 560} which means that iron-loaded liver tissue appears darker than paraspinous muscle. Whereas CT cannot quantify iron stores less than five times normal, gradient-echo MR allows quantification of iron stores that are minimally increased.^{555, 557, 561, 562, 563, 564}

Gradient-echo sequences allow quantification of storage iron that correlates well with chemical measurement of iron in a liver biopsy sample. Thus, MR scanning can provide credible estimation of the hepatic iron concentration in patients who, for any reason, do not undergo liver biopsy. After iron depletion, there is a decreased amount of attenuation of the gradient-echo signal, so the liver appears lighter than before.^{561, 562, 563, 564} Conventional T1-weighted and T2-weighted spin-echo MR⁵⁶⁵ or MR T2-star (T2*) imaging^{565, 566, 567, 568} can identify increased amounts of iron in myocardium and liver. Organs that are iron loaded have low signal intensity, so they appear dark on T2* MR images.

Chapter 26

Porphyrias

Sylvia S. Bottomley

The porphyrias are diverse disorders that arise from various inherited enzyme defects in the heme biosynthesis pathway (Fig. 26.1). The first authentic cases of porphyria were described in 1874.^{2, 3} Since that time, eight genetically distinct forms of porphyria have been characterized (Fig. 26.1; Table 26.1), each caused by a partial deficiency, and in one type by activation, of a different enzyme within the pathway (Table 26.2). The genes encoding these enzymes have been cloned, their chromosomal location is defined, and DNA analyses have revealed many heterogeneous molecular defects in all the porphyrias. The biosynthetic blocks resulting from the defective enzymes are expressed either in the liver or in the bone marrow, the sites where most of body heme is produced. The clinical and pathologic phenotype of each porphyria is dictated by effects of the associated enzyme defect and the mode of inheritance (Table 26.2) and is often influenced by

certain metabolic and environmental factors that affect the tightly regulated heme pathway. In some “late-onset porphyrias,” acquired clonal hematopoietic disorders may harbor a somatic mutation involving a heme synthesis enzyme that contributes to the expression of the porphyria.

Although the pathophysiologic mechanisms of the clinical manifestations of the porphyrias are only partly understood, two cardinal features prevail: cutaneous photosensitivity and neurologic symptoms of intermittent autonomic neuropathy, motor nerve palsies, and central nervous system disturbances. The cutaneous photosensitivity is a manifestation of the unique fluorescent properties of the porphyrins (the oxidized forms of the natural porphyrinogens in the heme synthesis pathway) that accumulate in those porphyrias in which the enzyme defects cause porphyrin accumulation (Fig. 26.1). The neurologic manifestations are associated with increased production of the porphyrin precursors 5-aminolevulinic acid (ALA) and porphobilinogen (PBG), which characterize the acute or inducible porphyrias. Among some of these, however, photosensitivity occurs as well if the enzyme defect also leads to accumulation of porphyrins. The distinguishing clinical manifestations of the porphyrias form the basis for the classification in Table 26.1. The diagnosis of a specific porphyria is ascertained by its characteristic profile of accumulated and excreted metabolic intermediates of the heme synthesis pathway (Table 26.2). It can be further confirmed by the activity of the affected enzyme but best by identification of the molecular defect causing the porphyria.

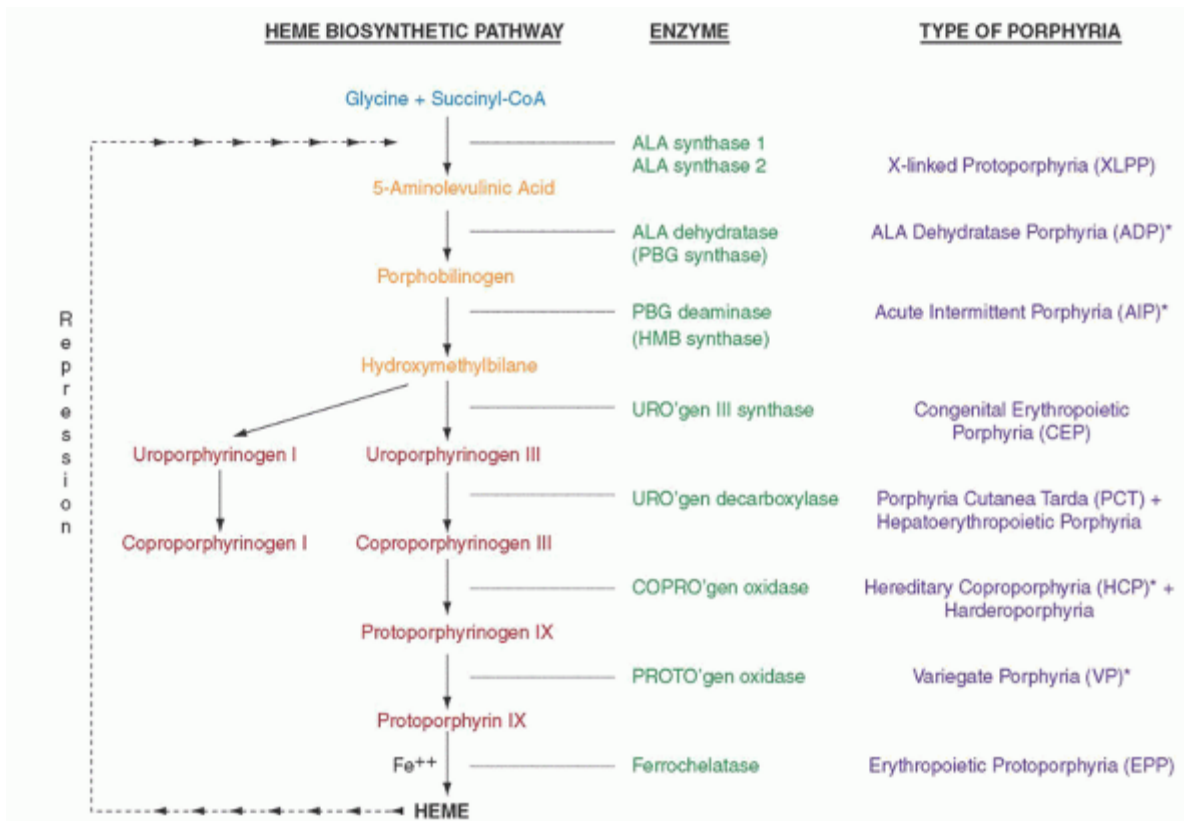

FIGURE 26.1. The heme biosynthetic pathway, its enzymes, and the eight forms of human porphyria associated with genetic defects of these enzymes. The major compound accumulated and excreted in excess in the seven porphyrias beyond the ALA synthase step is the substrate of the respective deficient enzyme; genetic defects in the erythroid ALA synthase (ALAS2) causing increased enzyme activity lead to increased flux of intermediates through the pathway and accumulated protoporphyrins. In the acute or inducible porphyrias (*), increased hepatic ALA production results from release of the normal negative feedback on ALA synthase exerted by heme, ¹ indicated by the trail of arrows. ALA, 5-aminolevulinic acid; Fe⁺⁺, ferrous iron.

TABLE 26.1 CLASSIFICATION OF THE PORPHYRIAS

I. Porphyrias with only cutaneous photosensitivity

Congenital erythropoietic porphyria (CEP)

Porphyria cutanea tarda (PCT); hepatoerythropoietic porphyria (HEP)

Erythropoietic protoporphyria (EPP)

X-linked protoporphyria (XLPP)

II. Acute porphyrias with only neurologic manifestations

Acute intermittent porphyria (AIP)

ALA dehydratase porphyria (ADP)

III. Acute porphyrias with both neurologic manifestations and cutaneous photosensitivity

Variegate porphyria (VP)

Hereditary coproporphyria (HCP)

IV. Dual porphyrias

PORPHYRIAS WITH CUTANEOUS PHOTOSENSITIVITY

Congenital Erythropoietic Porphyria

Congenital erythropoietic porphyria (CEP; Gunther porphyria), the second least common of the porphyrias, is characterized by a marked accumulation in erythroid precursors of uroporphyrin and coproporphyrin, which are predominantly of the isomer I type because defects reside in the gene for the enzyme uroporphyrinogen III synthase (UROS; Fig. 26.1). Many marrow erythroblasts and immature circulating erythrocytes exhibit intense red fluorescence in ultraviolet light. The large amounts of porphyrins released from these cells cause the most intense photosensitivity of all the porphyrias.

TABLE 26.2 GENETIC AND METABOLIC FEATURES OF THE PORPHYRIAS

Type of Porphyria	Inheritance	Defective Enzyme	Gene (Symbol/Location) ^a	Enzyme Activity (%) ^b Heterozygote	Porphyrin/Precursor Accumulated/Excreted ^d	Route of Excretion	Tissue Source	Homozygote ^c
X-linked protoporphyria	X-linked	5-Aminolevulinate synthase 2	<i>ALAS2</i> /Xp11.21	2 to 3 times normal		Free and zinc protoporphyrin	Feces	Bone marrow
ALA dehydratase	Autosomal recessive	ALA dehydratase (PBG synthase)	<i>ALAD</i> /9q33.1	33.50	<10	ALA, coproporphyrin	Urine	Liver
Acute intermittent	Autosomal dominant	PBG deaminase (HMB synthase)	<i>HMBS</i> /11q23.3	50	1-16	PBG, ALA	Urine	Liver
Congenital erythropoietic	Autosomal recessive	Uroporphyrinogen III synthase	<i>UROS</i> /10q25.2-q26.3	50	1-20	Uroporphyrin I, coproporphyrin I	Urine	Bone marrow
Cutanea tarda	Autosomal	Uroporphyrinogen III cosynthase	<i>UROD</i> /1p34.3	50	3-27	Uroporphyrin I	Urine	Liver

	dominant, or acquired	nogen decarboxylase				yrin I + III, 7- COOH porphyrin	ne	
Hereditary coproporphyrin ia	Autosomal dominant	Coproporphyrinogen oxidase	<i>CPOX</i> /3q12 50	2-10 ^e		Coproporphyrin III^f, PBG^f, ALA^f	Feces, urine	Liver
Variiegata	Autosomal dominant	Protoporphyrinogen oxidase	<i>PPOX</i> /1q22 50	0-20		Protoporphyrin Coproporphyrin^f, PBG^f, ALA^f	Feces, Urine	Liver
Protoporphyrin a	Autosomal recessive	Ferrochelatase	<i>FECH</i> /18q2 50 1.3	<10		Free protoporphyrin	Feces	Bone marrow
Protoporphyrin a	"Pseudodominant" ^g	Ferrochelatase	<i>FECH</i> /18q2 50-70 1.3	20-30		Free protoporphyrin	Feces	Bone marrow

ALA, 5-aminolevulinic acid; PBG, porphobilinogen; HMB, hydroxymethylbilane.

^a Gene symbol and chromosomal location as listed in the Human Gene Mutation Database, located at <http://www.hgmd.org>.

^b Percentage of normal.

^c Often a compound heterozygote.

^d The major metabolite and route are shown in boldface. The route of porphyrin

excretion is determined by the number of carboxyl groups on the porphyrin and hence by its water solubility.

^e In harderoporphyrin the activity is 18% to 24% of normal (see text).

^f Increased in urine during acute attack; in VP urine coproporphyrin is increased when symptoms are only cutaneous.

^g One allele is mutant and the other allele is usually underexpressed (see text).

Probably first recognized by Schultz² and Baumstark³ in 1874, CEP was described comprehensively and distinguished from other porphyrias by Gunther in 1911.⁴ It is a very rare disease, with less than 200 cases reported. It occurs with equal frequency in males and females and in a wide variety of racial groups. Usually, the illness is first detected in infancy⁵ but, in a number of instances, was not apparent until later in life.⁶ All evidence is consistent with transmission of the disorder as an autosomal recessive trait.^{5, 7}

Molecular Basis and Pathogenesis

The pattern of porphyrin accumulation in CEP reflects a defect in the conversion of PBG to uroporphyrinogen III. This conversion requires two enzymes: PBG-deaminase (PBGD) and UROS (Fig. 26.1). Affected individuals are homozygotes or compound heterozygotes for mutations in the UROS gene that result in markedly reduced activity of UROS (1% to 20% of normal), leading to the overproduction of uroporphyrinogen I through nonenzymatic cyclization of the substrate hydroxymethylbilane in erythroid precursors.^{5, 7} In heterozygotes (parents and some siblings of

patients with the disease), the activity of the synthase is intermediate (approximately 50%) between that found in affected individuals and that in normal subjects.⁸ The UROS gene resides on chromosome 10 (10q25.2-q26.3)⁹ and has alternative promoters that generate identical housekeeping and erythroid-specific transcripts.⁷ Forty-six distinct mutant alleles have been identified and molecular defects include point mutations, deletions, insertions, splicing defects, intron branch chain mutations, and erythroid-specific promoter mutations.^{5, 7, 10} Approximately one third are homoallelic and about 20% of alleles remain undefined. The most common mutation (Cys73Arg) has occurred in one third of alleles (and in nearly one half of homoallelic cases) and correlates with the most severe phenotype of nonimmune hydrops fetalis, transfusion-dependent anemia from birth, or both, particularly in homoallelic cases.⁵ In most instances, mild forms of the disease have been heteroallelic or only one mutant allele could be identified. Residual enzyme activity of the mutant proteins expressed in prokaryotic systems, or gene promoter-reporter activities in cases of promoter mutations, have provided more precise genotype/phenotype correlations.^{5, 7, 11} However, in two instances marked divergence of phenotypic expression among siblings suggested undefined modifying factors.^{12, 13} In another family it was demonstrated that the clinical phenotype is markedly affected by co-inheritance of an activating (gain-of-function) mutation in the erythroid-specific 5-aminolevulinic synthase (ALAS2) gene.¹⁴

In addition, variant genetic forms of the CEP phenotype are described. (1) In two patients porphyrin patterns and enzyme assays were consistent with a uroporphyrinogen decarboxylase (UROD) rather than a UROS defect, and the presence of a second dyserythropoietic defect was suggested to account for the clinical severity.^{15, 16} (2) A variant caused by a mutation in the X-linked erythroid transcription factor GATA binding protein 1 (GATA1) demonstrated that CEP can result from a genetic defect in a transacting factor.¹⁷ (3) CEP has occurred as a milder form in later life.^{6, 18} Of 16 such cases, 8 were associated with a myelodysplastic syndrome; the pattern of excess porphyrins was characteristic of childhood-onset CEP but at lower concentrations and erythrocyte UROS activity was normal.¹⁸ Presumably UROS mutations could not be identified if only a minor clone of uroporphyrin cells harbors a somatic mutation; alternatively another gene that determines UROS activity remains a possibility. This late-onset form of CEP has been termed "erythropoietic uroporphyrin secondary to myeloid malignancy."¹⁸

Although defective UROS operating in the erythron characterizes the primary inherited abnormality, no overall deficiency of heme production is evident, perhaps because normal UROS activity appears to be the highest relative to all other heme biosynthetic enzymes in erythroid cells. It is more than 1,000 times greater than the activity of ALA synthase,¹⁹ the rate limiting enzyme, so that even very low residual enzyme activity seems to be sufficient to support normal or even increased rates of heme synthesis. Uroporphyrin I is the predominant urinary porphyrin, but increased excretion of uroporphyrin III also invariably occurs, implying up-regulation of the UROS or of enzymes higher up in the pathway. These findings are consistent with the idea that the pathophysiology of CEP is a result of the accumulation of uroporphyrin I rather than of subnormal production of uroporphyrinogen III and heme.²⁰ However, it is unclear why uroporphyrin I, not coproporphyrin I, is the main porphyrin excreted, which may relate to the relative UROD activity in normal erythroid cells being on the order of one tenth of that of UROS.¹⁹

The large amounts of porphyrins released from erythroid cells and deposited in multiple tissues²¹ exert the principal damage in the skin and subcutaneous regions through oxygen-dependent phototoxic reactions on excitation by light (see section "Porphyria Cutanea Tarda").^{22, 23} This relentless process leads in varying degrees to the formation of subepidermal bullae, secondary infection, scarring, epidermal atrophy, and resorption of acral structures. Laboratory parameters of hemolysis correlate with severity of anemia. Associated splenic sequestration leads to splenomegaly and variable leukopenia and thrombocytopenia. Whether photolysis of the porphyrin-laden erythrocytes occurs *in vivo* is not known.

Clinical Description

The first sign of this affliction is often discoloration of the infant's diapers by the urine, which ranges in color from pink to deep burgundy and fluoresces under Wood's light.²⁴ The most prominent manifestation is pronounced cutaneous photosensitivity. Exposure to visible light is followed by the development of vesicular or bullous lesions containing a porphyrin-rich, fluorescent fluid. The lesions tend to heal slowly, leaving pigmented scars (Fig. 26.2A). Often, they become infected, ulcerated, and necrotic. Over a period of years, patients develop progressive mutilation and disfigurement with loss of portions of the fingers, nose, eyelids, or ears (Fig. 26.2B). Corneal scarring can lead to blindness.⁵ Skin not exposed to light is unaffected. Hypertrichosis is prominent and fine hair growth may cover much of the face and extremities. The patients often adopt extreme precautions to avoid the sun. Deposition of porphyrin in the dentin of the teeth causes them to appear red (erythrodontia), brown, or yellowish. Even if discoloration is not apparent in ordinary light, the teeth exhibit

red fluorescence in ultraviolet light. At necropsy, the entire skeleton has this red fluorescence.²¹ Osteopenia and osteolytic lesions can occur.²⁵

Anemia, the result of both hemolysis and ineffective erythropoiesis, is detected in most patients, and usually the spleen is enlarged. The most severe phenotypes are transfusion-dependent.

Laboratory Findings

The anemia is normocytic, normochromic, and of variable severity. Detailed morphologic descriptions of the blood and bone marrow have been reported in a few patients. Anisocytosis, poikilocytosis, polychromasia, basophilic stippling, and nucleated erythrocytes are fairly common features of the peripheral blood.²⁶ Following splenectomy, needlelike fluorescent red cell inclusions that may represent precipitated porphyrin have been observed.²⁷ Morphologic abnormalities of the bone marrow range from erythroid hyperplasia to striking dyserythropoiesis.^{5, 17, 26, 28} Nuclear inclusions containing hemoglobin may be present.^{15, 28} Results of studies of the marrow with light and fluorescence microscopy suggest the coexistence of normal and abnormal erythropoietic cells.^{15, 28} Fluorescence is restricted to the morphologically abnormal cells and is most marked in cell nuclei.^{15, 28, 29} Evidence of a dual nature of the erythroid precursors has been supported by ultrastructural studies in two cases.^{15, 30} Kinetically, the anemia is characterized by both a shortened red cell survival and ineffective erythropoiesis.³¹ Its morphologic and kinetic features closely resemble those of congenital dyserythropoietic anemia type I (Chapter 40).

The most characteristic metabolic abnormality is greatly increased urinary excretion of uroporphyrin I, a biologically useless isomer that cannot be converted to heme. Urinary excretion of uroporphyrin III and coproporphyrins I and III is also increased but to a lesser extent than uroporphyrin I.^{5, 20} Total urinary porphyrin excretion may exceed 100,000 µg daily (normal is <300 µg), and the urine usually fluoresces on exposure to ultraviolet light. Fecal excretion of porphyrins, especially coproporphyrin I, is greatly increased.²⁰ The concentration of uroporphyrin I is increased in erythrocytes and plasma, but the marrow porphyrin content exceeds that of the peripheral blood or other tissues.²⁰

Treatment

Splenectomy may partially or completely relieve the hemolytic anemia and may also lead to reduced porphyrinuria and

P.685

photosensitivity.^{26, 27, 28} However, this operation is not always beneficial³² and is not always warranted by the degree of anemia. Suppression of erythropoiesis by transfusion decreases porphyrin excretion.^{5, 33} A young boy with CEP was successfully treated with chronic hypertransfusion;³⁴ transfusion-induced iron overload was avoided by means of concomitant iron chelation therapy. After puberty, his relapse on this regimen was controlled with the addition of hydroxyurea.³⁵

FIGURE 26.2. Congenital erythropoietic porphyria. A: In an Indian boy. Note facial hypertrichosis, scarring, and discoloration of the teeth. B: In a 50-year-old Caucasian man. Note the severe photomutilation. (Courtesy of Dr. Neville Pimstone, University of California, Davis, CA.)

Another patient was treated successfully with long-term orally administered charcoal at a dose of 60 g three times daily.³⁶ Oral charcoal appeared to act by binding porphyrins excreted in bile and serving as a sump that diverted circulating and skin porphyrins to a fecal route of elimination in two cases^{37, 38} but had no effect in others.⁵ In two patients, severe anemia improved with administration of the antioxidants α -tocopherol and ascorbic acid.²⁵ Hematopoietic stem cell transplantation (HSCT) remains the only known curative treatment and to date was successful in 17 of 21 patients.^{5, 7, 39}

In theory, the most definitive method to control the disease would be transfer of the normal gene into hematopoietic stem cells of the affected patient. After *in vitro* correction of the enzyme defect by viral transfer of the normal gene into deficient cells, long-term correction of the disease in CEP mice had provided support for hematopoietic stem cell gene therapy clinical trials, and gene correction of CEP-derived iPSCs (induced pluripotent stem cells) was recently achieved to circumvent potential proviral insertional leukemogenesis.⁴⁰ In another approach, the function of the common mutant protein Cys73Arg could be rescued with a proteasome inhibitor in cultured cells.⁴¹ Prenatal diagnosis or exclusion of the disorder is possible with enzyme assay or DNA analysis of amniotic fluid cells.^{42, 43}

Most patients must rely on avoidance of exposure to sunlight. They should be instructed to wear photoprotective clothing, including gloves and broad-brimmed hats. Conventional sunscreen agents are ineffective because they do not screen out the wavelengths in the Soret band of the nearly visible spectrum (around 400 nm) that are responsible for inducing porphyrin-mediated photosensitivity.⁴⁴ To be effective, a local agent must be visible on the skin. Reflective materials, such as zinc oxide and titanium oxide, are useful, as is ordinary pigmented theatrical makeup.⁴⁵ Preparations containing substituted quinones (such as 2-hydroxyl-1,4 naphthoquinone, also known as hemotannic acid or Lawsone) and dihydroxyacetone turn the skin a cosmetically acceptable brownish-tan and may be effective. Therapy with β -carotene beadlets may also offer some protection from the deleterious effects of light (see section "Erythropoietic Protoporphyrin"). A single-observer clinical study of 29 CEP cases together with a proposal for a management algorithm derived from the patient cohort has recently been presented.^{39, 46}

Congenital Erythropoietic Porphyria in Animals

CEP (pink tooth) in cattle appears to be milder than the human disorder. The disease is inherited as an autosomal recessive trait, and heterozygous animals are clinically and biochemically normal,^{47, 48} although an increased ratio of

coproporphyrin I to coproporphyrin III in the urine was reported.⁴⁹ Photosensitivity of the skin areas not covered by pigmented hair and hemolytic anemia are observed. The teeth and bones are stained red. UROS activity is severely impaired in erythrocyte lysates.⁵⁰

A similar disorder has been observed in pigs and cats.^{51, 52} A naturally occurring feline CEP was recently characterized by clinical phenotype, biochemical analysis, and molecular studies.⁵³ In the fox squirrel (*Sciurus niger*), as part of the apparently normal physiology of the species, large amounts of uroporphyrin I are deposited in the tissues and excreted in the urine.⁵⁴ As in human CEP, the normoblasts and young erythrocytes show a red fluorescence; however, hemolytic anemia is lacking, and the fox squirrel seems to suffer no ill effects. Erythroid UROS activity is lower than that found in the closely related but nonporphyric gray squirrel (*Sciurus carolinensis*).⁵⁴

In knockin mouse models of patient mutations, the phenotypes closely resemble the human disorder.^{55, 56} These mice would appear suitable for studies of pathogenesis and therapies in CEP.

P.686

Porphyria Cutanea Tarda

Porphyria cutanea tarda (PCT) is the most commonly encountered porphyric disorder. It results from reduced activity of UROD (Fig. 26.1) in the liver, leading to accumulation of uroporphyrins (oxidized uroporphyrinogens), their release into plasma, and excretion in the urine.²⁰ Clinical manifestations are limited to the skin in the form of a photosensitive bullous dermatosis as a consequence of the circulating uroporphyrins. Neurovisceral symptoms never occur. Symptoms usually arise in mid- or later life (hence the name tarda) and are nearly always brought on by genetic and environmental factors, most often hepatic siderosis, alcohol abuse, hepatitis C virus, and estrogen therapy. Since the first comprehensive description of the disease in 1937,⁵⁷ three variant forms of the illness have been recognized: familial, sporadic, and toxic.

Molecular Basis and Pathogenesis

Among the variants of the disorder, a genetic basis has been established for one, designated familial PCT (type II), but it accounts on average for only 20% to 30% of cases.^{58, 59, 60, 61} Studies of patients with subnormal UROD activity in both hepatic and extrahepatic tissues, and their relatives, revealed that the enzyme defect is inherited as an autosomal dominant trait.^{62, 63, 64, 65} Enzyme activity is one-half normal in all tissues, as is the amount of UROD protein detected with antibodies.^{66, 67, 68} In the rare homozygous form, designated hepatoerythropoietic porphyria (HEP), residual enzyme activity ranges from 3% to 27% of normal,^{20, 68, 69, 70, 71} but immunoreactive enzyme is variable.^{67, 68, 72} Since the cloning of the human UROD gene,⁷³ located on chromosome 1 (1p34),⁷⁴ at least 113 different mutations in the gene have been identified.^{10, 75} Usually, a given mutation is found in one or in a few kindreds only. The majority are various point mutations in the coding region of the gene or splice site mutations, resulting in changes of amino acids, frameshifts, or deletions; in some instances, large nucleotide deletions were detected. The defects usually result in the production of an unstable or inactive enzyme from the mutant allele. Functional consequences of many of the mutations have been defined or predicted on the crystal structure of the enzyme.^{76, 77} In the homozygous version among about 40 cases reported, 15 different mutations have been identified.^{10, 75, 78} The mutations are homoallelic or heteroallelic, causing instability or impaired catalytic activity of the enzyme, and survival hinges on residual enzyme activity encoded by the alleles.

When reduced UROD activity is restricted to the liver and a genetic basis for the disorder is not evident, it is called sporadic PCT (type I).^{64, 66, 79} Both the catalytic activity and the immunoreactivity of erythrocyte UROD are normal in this variant.^{67, 79} In the liver, catalytic activity of UROD is subnormal, but immunoreactive enzyme is present in normal or increased amounts.⁷⁹ After prolonged remission is induced by phlebotomy therapy, both catalytic activity and immunoreactivity become normal.⁸⁰ These findings, coupled with lack of a family history in most cases of sporadic PCT, have implied that this form of the disease is acquired and not inherited. At the molecular level, no mutations could be found in the UROD gene or its promoter region.⁸¹ However, in a few families, clinically manifest PCT was associated with decreased UROD activity in liver and normal activity in erythrocytes and other tissues.⁷⁵ These cases were called type III PCT; molecular studies have not identified UROD mutations in them.⁸²

The cutaneous damage produced by the accumulated uroporphyrins in plasma and skin of patients with PCT is the consequence of the fundamental properties of the porphyrins. As they absorb light at 400 to 410 nm (Soret band), not only does their photoexcitation yield energy as fluorescence, but in the aerobic environment of tissues, reactive oxygen species (superoxide anion and other reactive metabolites) are produced⁴⁴ that are damaging to cells. In vivo, superoxide

anions are generated by activation of xanthine oxidase.⁸³ The complement system is light activated in vitro in sera containing porphyrins and in vivo in the skin of porphyric patients, promoting release of proteases from dermal mast cells.²³ Chemotactic activity is also generated under these conditions, and the peroxides produced by photoexcitation of the porphyrin and those arising from polymorphonuclear leukocytes with activation of the complement system may act synergistically to contribute to the development of the cutaneous lesions. As a consequence of these events, the dermal-epidermal junction becomes disrupted and leads to skin fragility and the formation of vesicles and bullae that easily rupture. Sclerodermoid changes of the skin result from a light-independent effect (the “dark effect”) of the uroporphyrin on collagen synthesis by skin fibroblasts.⁸⁴ The pathogenesis of the hyperpigmentation, hypopigmentation, and hypertrichosis is not understood.

Most family members carrying a defective gene of familial PCT do not have clinically apparent disease but a significant number have increased excretion of porphyrins;⁷⁷ in occasional pedigrees, overt manifestations of the disease were noted in several generations.⁶³ Clinical expression of both familial and sporadic PCT is nearly always associated with prevalent confounding factors that cause hepatic injury, so the disorder remains silent without these. In large series of PCT, most patients had more than one of four cardinal hepatotoxic risk factors, namely hepatic iron excess, excessive alcohol use, viral infection (hepatitis C), and medicinal estrogens,^{60, 61, 85} although these are far more common than the estimated frequency of PCT (approximately 1 per 25,000).²⁰

Hepatic Iron

The central role of iron in the clinical expression of PCT has been recognized for 52 years.^{86, 87} Numerous studies documented hepatocellular siderosis in most patients with significant uroporphyrinuria.^{88, 89, 90} The iron deposits generally are moderate in amount, 1.5 to 4 times normal, but are usually greater with co-inheritance of hemochromatosis susceptibility alleles (Chapter 25).^{88, 91, 92, 93} Except for the geographic variation in the frequency of the hemochromatosis HFE alleles,^{75, 94} on average, 35% of patients with PCT are heterozygous for the Cys282Tyr mutation, and 15% are homozygous or double heterozygotes with the His63Asp mutation.^{60, 61, 85, 94} The cause of excess hepatic iron in the remaining cases appears to result from down-regulation of hepcidin expression regardless of iron status and consequent to the oxidative stress associated with the other risk factors for PCT.⁹⁵ However, in another study serum hepcidin levels were found increased.⁹⁶ Transfusional iron overload also promotes clinical expression of PCT.⁹⁷

Depletion of iron by repetitive phlebotomy⁹⁸ or by administration of deferoxamine⁹⁹ uniformly induces both clinical and biochemical remissions. Replenishment of iron stores promptly reignites symptoms in patients in whom a remission has been induced by phlebotomy.^{88, 100} The explanation for the provoking influence of iron is based on studies in mouse models, which indicate that the hepatic UROD activity of 50% in UROD-deficient animals must be reduced to 20% or less of normal in order for PCT to be manifest and is achieved by concomitant iron overload.^{101, 102} An inhibitor of the enzyme was found in liver cytosol of these animals, as well as of PCT patients, and is a porphomethene that is generated by iron-dependent partial oxidation of uroporphyrinogen via catalysis by cytochrome P4501A2 (CYP1A2) or another enzyme.^{103, 104} This is consistent with the diminished hepatic UROD activity without reduction in enzyme protein in symptomatic PCT patients and the restoration of hepatic UROD activity to its genetically determined level after iron depletion.^{60, 79, 80} The mechanism for the generation of sufficient inhibitor in patients with sporadic PCT that does not occur in iron overload states in general remains to be defined. The oxidative environment in the

P.687

hepatocyte generated by the common environmental risk factors accompanying clinical expression of the disorder, as well as other traits such as the allele variants of CYP1A2 and G51M1A,¹⁰⁵ probably play an important role.⁹⁴

Alcohol

Ethanol exacerbates PCT. Heavy alcohol intake was found in 25% to 100% of patients in many studies,^{60, 61, 85, 89, 94, 106} and hepatic cirrhosis is not uncommon.^{89, 90} Yet the porphyria is an uncommon complication of alcoholic liver disease, occurring in only approximately 2% of cases.¹⁰⁷ The association of clinically expressed PCT with alcoholism would relate to its hepatotoxicity and its effect of stimulating iron absorption.¹⁰⁸ In this regard, PCT is particularly common among the Bantu population of South Africa, where it is associated with excessive consumption of alcoholic beverages brewed in iron containers,¹⁰⁹ thus providing a double threat to susceptible people. Studies have suggested that an undefined hemochromatosis gene plays a role in the iron overload of this population when iron intake is excessive (Chapter 25).¹¹⁰

Hepatitis C

A striking association between symptomatic PCT, familial and sporadic, and hepatitis C is well recognized but is variable around the world. Although most patients with hepatitis C infection do not have the porphyria, as many as 80% of PCT patients are chronically infected with the virus in some locations.^{60, 61, 75, 94, 111} This infection elicits oxidative stress in hepatocytes as well as down-regulation of hepcidin expression⁹⁴ and would explain, at least in part, the liver damage often found in PCT. Association of PCT with human immunodeficiency virus (HIV) infection also occurs,¹¹² and such patients may be infected with both HIV and the hepatitis C virus.^{94, 112, 113} Dual infection causes more severe hepatic disease; whether the HIV virus per se plays a role in the expression of PCT is not known. Thus, patients should be evaluated for the presence of hepatitis C and HIV at the time of diagnosis.

Estrogens

The association of estrogen ingestion and expression of PCT has been reported numerous times but occurs only in a very small percentage of patients who ingest estrogens, consistent with an underlying predisposition to the disease. The cutaneous symptoms have occurred with the use of estrogen as a post-menopausal supplement,⁶⁰ for contraception,¹¹⁴ and for prostatic carcinoma.¹¹⁵ Uncommonly, patients present with the disorder during pregnancy,¹¹⁶ but pregnancy has also not exacerbated PCT.¹¹⁷ The mechanism of the estrogen effect is thought to relate to its adverse effects on the liver such as steatosis and steatohepatitis. It is generally a lesser factor, as venesection alone has brought about full recovery. Most women needing estrogen supplements at the usual dose can probably use them, provided that storage iron is removed and maintained at a low level.

Other Susceptibility Factors

Additional susceptibility factors that are positively associated with PCT are smoking, allele variants of CYP1A2 and GSTM, and ascorbic acid deficiency.^{61, 105, 118, 119} Several diverse drugs and radiation have also been implicated in precipitating PCT in a few cases.

Renal Failure

PCT occurs in patients with renal failure undergoing hemodialysis.¹²⁰ Symptoms may first arise in this setting for several reasons. Iron overload is not uncommon in such patients, and intravenous iron used in conjunction with erythropoietin for the anemia may precipitate clinical PCT.¹²¹ Hemodialysis or peritoneal dialysis does not effectively clear circulating plasma uroporphyrins,^{122, 123} presumably because porphyrins are bound to proteins.¹²⁴ The uremic state may also contribute to an inhibited UROD and uroporphyrin accumulation independent of an underlying enzyme defect or inhibition.¹²⁵ In most reported cases, the lack of family or molecular studies makes it difficult to classify the porphyria.

Clinical Description

Cutaneous changes represent the clinical manifestations of PCT.^{20, 89} Skin lesions are found predominantly on light-exposed areas such as the face and hands and, in women, on the legs and feet as well. There is little discomfort with sun exposure per se, and blue (visible) light triggers only an insidious cutaneous damage. The most common complaint is marked skin fragility in areas subjected to repeated minor trauma, such as the hands and forearms (Fig. 26.3). Vesicles and bullae form primarily on the dorsa of the hands and may erode, leaving atrophic scars that often display zones of both hyperpigmentation and hypopigmentation. Small, 1- to 2-mm, firm, whitish papules (milia) are commonly noted on the hands and, at times, on the face.

Facial hypertrichosis occurs in most patients, is generally more noticeable in women, and may be an isolated presenting feature.¹²⁶ Hypertrichosis, sometimes striking, is occasionally observed on areas of the skin that are rarely exposed to the sun, such as the trunk and legs. Other findings include hyperpigmentation of facial skin, alopecia, and scleroderma-like changes on the skin of the face, neck, and hands. The histologic appearance of the scleroderma-like lesions is identical to that seen in patients with systemic scleroderma.⁸⁹ Occasionally, patients have overt signs and symptoms of underlying liver disease, but no good correlation exists between the degree of liver disease and the occurrence or severity of the porphyria.

In the homozygous form of familial PCT, or HEP, the skin changes just described usually occur before the age of 5 years and photosensitivity may be severe, resembling CEP and including disfigurement.^{75, 78} Developmental delay and seizures have also been reported. Other features are pink urine, dental fluorescence, and occasionally hepatosplenomegaly. Severity of clinical manifestations can vary in affected children within a family; in some instances the clinical phenotype is unusually mild.^{78, 127}

Laboratory Findings

Patients with symptomatic PCT excrete greatly increased amounts of porphyrins in the urine. Uroporphyrin and heptacarboxylic porphyrin predominate, with lesser amounts of coproporphyrin and small amounts of 5- and 6-carboxylate porphyrins.^{89, 128} Usually, the daily urinary excretion of uroporphyrin is approximately 3,000 µg (normal, <50 µg), but considerably higher values may be found. Uroporphyrin in the urine is predominantly isomer I, whereas the heptacarboxylic porphyrin is predominantly isomer

P.688

III.^{20, 89} Photosensitive cutaneous symptoms rarely occur when the daily urinary excretion of uroporphyrin is <1,000 µg. Urinary coproporphyrin rarely exceeds 600 µg daily.⁸⁹ An unusual and distinctive tetracarboxylic porphyrin, isocoproporphyrin, is excreted in feces,¹²⁹ and a slight increase may be noted in total fecal porphyrin excretion.²⁰ Plasma porphyrin level is typically increased, with a fluorescence peak at neutral pH near 619 nm. Homozygotes for the defect have mild anemia; it was severe in three cases.⁷⁵ The erythrocyte protoporphyrin was found to be moderately increased when measured and is primarily zinc protoporphyrin.^{75, 78}

FIGURE 26.3. Porphyria cutanea tarda in a 60-year-old man. Note denuded skin areas over the fingers, an erosion, blisters, and milia.

The serum iron concentration and, hence, transferrin saturation are commonly increased as is the serum ferritin level.^{60, 89} Values for liver function tests vary considerably from one case to another. Some patients have mild degrees of jaundice and slight to moderate elevations in serum transaminase levels. Liver biopsy specimens display characteristic reddish-pink fluorescence.^{89, 90, 130} On microscopic examination, siderosis, periportal inflammation, focal necrosis, fatty infiltration, and some evidence of fibrosis are common findings.^{89, 90, 130, 131} Often, fluorescent and birefringent needle inclusions are noted.¹³¹ Electron microscopic studies reveal needlelike lucent areas, which appear to be in lysosomes.¹³² Microscopic examinations of skin biopsy specimens show bullae formed by the separation of the epidermis from the dermis; periodic acid-Schiff-positive, diastase-resistant material around vessel walls in the upper dermis; and a sparse inflammatory cell infiltrate.^{89, 133} Immunofluorescence studies display deposition of immunoglobulin G (and less often immunoglobulin M) or complement around upper dermal vessels and at the dermal-epidermal junction.¹³³

Treatment

Exposure to alcohol and excessive estrogen supplements in women, as well as smoking, should be avoided. Abstinence from alcohol can lead to remissions in some patients with the porphyria associated with alcoholic liver disease, but removal of iron by phlebotomy can induce remissions even if alcohol intake continues.^{98, 134} It is of interest that occasionally remission has been achieved in patients with PCT and hepatitis C after antiviral treatment alone.¹³⁵ Conversely, poor response to interferon- α is common in patients with hepatitis C and PCT.¹³⁶ Transdermal administration of estrogen was found to be safe in a small number of patients¹³⁷ and avoids any possible first-pass effects of the hormone on the liver.

The definitive treatment of both sporadic and familial PCT is the removal of iron stores by phlebotomy, which leads to clinical and biochemical remission in virtually every case and may improve concomitant hepatitis C virus infection. It is recommended that any antiviral therapy be deferred until a de-ironed state is reached.⁹⁴ If there are no contraindications, 500 ml of blood is removed every 1 to 2 weeks. Initial serum transferrin saturation and ferritin values are obtained to estimate the iron burden. Liver biopsy must also be considered to assess the disease status of associated viral hepatitis and hemochromatosis. Clinical remissions often occur after the removal of approximately 3 L of blood;^{89, 98} patients who also have hemochromatosis usually require considerably more therapy and indefinite regular maintenance phlebotomies. The optimal approach is to achieve mild iron deficiency, defined by onset of iron-limited erythropoiesis in which the mean corpuscular volume is decreased to low normal, the serum transferrin saturation is low normal, and the serum ferritin is near 20 $\mu\text{g/L}$ or lower. Although further overproduction of uroporphyrins is halted thereafter, the chronically accumulated, relatively hydrophobic porphyrins are released slowly from the liver. Patients should be advised that formation of new skin lesions ceases gradually, and full recovery often extends over several months to a year or more.⁸⁹ Remissions for years are the rule^{89, 98} and are permanent when the known precipitating factors are avoided or removed; any clinical and biochemical relapse responds to another course of phlebotomies.^{89, 98}

Hydroxychloroquine and chloroquine have also been used in the treatment of PCT. After the administration of chloroquine (0.5 to 1.0 g/day) for several days, a large amount of the porphyrins stored in the liver was mobilized and excreted in the urine.¹³⁸ This purging effect results from the formation of an easily excreted water-soluble complex between uroporphyrin and the drug.¹³⁹ The chloroquine effect was often accompanied by malaise, anorexia, fever, and signs of hepatocellular damage. Subsequent use of lower doses made it possible to avoid the toxic response without impairing efficacy,¹⁴⁰ but this maneuver does not always preclude toxicity.⁸⁹ Because of the potential danger of the hepatic reaction to antimalarials and because phlebotomy is usually safe and effective, administration of low doses of hydroxychloroquine or chloroquine should be reserved for patients for whom phlebotomy is unsuitable. Moreover, patients with HFE hemochromatosis appear not to respond to this therapy.¹⁴¹

The use of sunscreen agents effective in the Soret band of the spectrum and avoidance of sunlight through protective clothing can be useful until the beneficial effects of phlebotomy are achieved. These measures are the principal means to help patients with the homozygous form of PCT in whom phlebotomy is not effective. The antimalarials may be beneficial in these individuals.⁷⁵ Severe anemia and cutaneous symptoms responded to erythropoietin in one case.¹⁴² Efforts toward somatic gene therapy were initiated by demonstrating correction of the enzyme defect with retroviral gene transfer in vitro in transformed B-cell lines¹⁴³ and may become a prospect in vivo as noted for CEP. Prenatal exclusion of HEP has been possible.¹⁴⁴

Treatment of patients with PCT and renal failure presents special challenges. The disorder may be particularly severe because such patients lack the renal excretory pathway for porphyrins, leading to higher porphyrin levels in plasma and tissues. Chloroquine-porphyrin complexes are not filtered out by standard hemodialysis. High-flux hemodialysis appears to remove porphyrins from plasma better and may be of some benefit.¹⁴⁵ The treatment of choice is administration of recombinant erythropoietin to mobilize stored iron and relieve the anemia so that phlebotomies can be performed as necessary to induce remission.^{146, 147} This method is preferable to the alternative of depleting iron stores with iron chelation.¹⁴⁷ In patients refractory to these treatment methods, the porphyria fully resolved after renal transplantation.¹⁴⁸

Toxic Porphyria Cutanea Tarda

In Turkey between 1956 and 1961, an epidemic of acquired porphyria affecting more than 3,000 people occurred as the result of exposure to flour contaminated with a seed-wheat fungicide, hexachlorobenzene.^{149, 150, 151} Members of both sexes were affected, and many of the subjects were children. Affected people developed hepatomegaly, hypertrichosis, hyperpigmentation, uroporphyrinuria, and a photosensitive dermatosis. Uroporphyrinuria and a variety of other signs and symptoms persisted in some individuals for more than 25 years,^{152, 153} and no effective therapy has been devised for this toxic porphyria. Studies in animals demonstrated that hexachlorobenzene, or one of its metabolites, is a potent inhibitor of hepatic UROD.^{154, 155} Iron magnifies this inhibitory effect,¹⁵⁴ and clear genetic susceptibility to this type of acquired porphyria has been shown in mice.¹⁵⁶

Other polyhalogenated aromatic hydrocarbons also have produced a toxic porphyria in humans. 2,3,7,8-Tetrachlorodibenzo-p-dioxin, a by-product in the manufacture of the herbicides 2,4-dichlorophenoxyacetic acid, 2,4,5-trichlorophenoxyacetic acid, and some polychlorinated biphenyls have proved porphyrinogenic for humans.¹⁵⁷ Animal studies indicate that compounds

P.689

of this class inhibit hepatic UROD activity.¹⁵⁸ As in the case of hexachlorobenzene-induced porphyria, iron magnifies the inhibition of UROD, and iron depletion minimizes the inhibitory effect of these agents.¹⁵⁹ The parallel between the permissive effects of iron in these toxic porphyria models and the role of iron in the pathogenesis of both familial and sporadic PCT is striking.

Hepatocellular Carcinoma

An increased frequency of hepatocellular carcinomas is recognized in patients with PCT,^{160, 161, 162} and such tumors are associated with a long symptomatic period before the start of treatment as well as with the presence of cirrhosis or chronic active hepatitis.¹⁶¹ The body iron status is not known in these cases, but iron overload could also play a role. Thus, in the presence of hepatitis or cirrhosis, surveillance for hepatocellular carcinoma with regular hepatic imaging is indicated.

In contrast, documented evidence supports a PCT-like illness as a manifestation of porphyrin-producing hepatoma in an otherwise normal liver (paraneoplastic PCT) in several cases.^{163, 164, 165, 166} When the tumor could be surgically removed, the cutaneous symptoms and biochemical abnormalities remitted.^{163, 166}

Animal Models of Porphyria Cutanea Tarda

The first genetically designed animal model of PCT and HEP was developed in zebrafish, designated yquem.¹⁶⁷ Heterozygous and homozygous mutants have 67% and 36% of wild-type UROD activity, respectively. The enzyme deficiency was linked to a missense mutation in the UROD gene, predicting a Met38Arg substitution that involves a conserved amino acid across all species examined, including humans. The mutant phenotype could be rescued by transient and germline expression of the wild-type allele.

Transgenic mice with one disrupted UROD allele (UROD^{+/-}) have half the wild-type hepatic UROD protein and enzyme activity but no accumulation of porphyrins.¹⁰¹ However, in response to iron loading, hepatic porphyrins accumulate, and UROD activity declines to 20%. When bred to HFE^{-/-} mice, UROD^{+/-}/HFE^{-/-} animals developed a porphyric phenotype with further reduction of UROD activity to 14%, resembling the human condition.

HFE^{-/-} mice that are fed ethanol also develop uroporphyrin and reduced hepatic UROD activity, seemingly mediated by effects of ethanol on hepatic iron metabolism.¹⁶⁸ Additional mouse models have been informative for understanding the susceptibility factors in PCT. CYP1A2 knockout mice are highly resistant to developing uroporphyrin induced by chemicals.¹⁶⁹ In mice that are genetically unable to synthesize ascorbic acid, a threshold of body iron was demonstrated at which a biphenyl-induced uroporphyrin accumulation occurs despite ascorbate repletion.¹⁷⁰ Extensive study of such animal models of hepatic uroporphyrin has provided a paradigm of the complex interactions among genetic factors, chemicals, drugs, and endogenous factors including iron homeostasis.¹⁷¹

PCT was identified in a flock of German Blackface sheep with clinical features similar to human PCT.¹⁷² It is associated with a point mutation in the UROD gene, predicting the amino acid substitution Leu131Pro, which is located in the active site cleft of the UROD protein.

Erythropoietic Protoporphyrin

Erythropoietic protoporphyria (EPP), the third porphyric disorder with only cutaneous manifestations, is not uncommon, with an estimated prevalence of 1 per 75,000 to 200,000. Since the first clear description of the disease by Magnus et al. in 1961,¹⁷³ hundreds of cases have been reported throughout the world.^{20, 174, 175, 176} Defects in the gene encoding ferrochelatase (FECH), the last enzyme in the heme biosynthetic pathway (Fig. 26.1), underlie most cases and result in accumulation of free protoporphyrin, mainly in erythroid tissue. The cutaneous manifestations are distinctive, but considerable individual variation is noted in clinical severity as well as in biochemical abnormalities. Three patterns of inheritance are recognized for the disorder (Table 26.2), and two variants occur.

Molecular Basis and Pathogenesis

Subnormal FECH activity is found in all tissues examined from patients with EPP, namely bone marrow,¹⁷⁷ reticulocytes,¹⁷⁸ liver,¹⁷⁹ cultured skin fibroblasts,¹⁷⁹ and lymphocytes.¹⁸⁰ However, the protoporphyrin accumulates principally, if not

entirely, in erythroid cells,¹⁸¹ whose contribution to heme production far exceeds that of all other tissues. Although the normal relative activity of FECH in erythroid tissue, in contrast to liver, is the second lowest among the enzymes of the heme biosynthetic pathway and is only three times higher than 5-aminolevulinate synthase,¹⁹ defective FECH in EPP does not appear to be rate limiting until late in erythroid development.¹⁷⁷ Patients often exhibit a mild hypochromic-microcytic anemia as a consequence of the FECH deficiency that in turn appears to limit iron assimilation.^{177, 182, 183, 184} Protoporphyrin begins to accumulate in bone marrow erythroblasts just before the nucleus is lost,¹⁸⁵ and reticulocytes and young erythrocytes probably are the major source of protoporphyrin in plasma on its rapid release from these cells.^{186, 187} Because of its low water solubility, the protoporphyrin is not excreted in urine but is taken up by the liver and excreted exclusively through the biliary tract.

Based on clinical features and FECH activity in many pedigrees, inheritance of this porphyria was first believed to most often follow an autosomal dominant pattern with incomplete penetrance.^{183, 188} In a few families, autosomal recessive inheritance was evident.^{174, 189} However, FECH activity in tissue lysates from patients with clinical EPP is always only 20% to 30% of normal,^{20, 181} not the 50% value expected for an autosomal-dominant enzyme deficiency. Neither levels of FECH activity nor levels of erythrocyte and fecal protoporphyrin consistently correlate with severity of symptoms. Moreover, most obligate carriers of the disorder have no symptoms. Their erythrocyte and fecal protoporphyrin levels are usually normal, and tissue FECH activity is approximately 50% of normal.^{20, 179, 181} To explain these findings, it was proposed that more than one allele is involved in the full expression of the disease.^{174, 190}

Upon the cloning and characterization of the human FECH gene,¹⁹¹ which is located on chromosome 18 (18q21.3),¹⁹² at least 187 different molecular defects have been identified and are highly heterogeneous, commonly as missense/nonsense mutations, nucleotide deletions and insertions, and intronic point mutations near intron/exon splice sites in one FECH allele.^{10, 192a} Most often, the defects lead to frameshifts or deletions, resulting in a truncated protein ("null allele"). The entire FECH gene was absent in one patient as a result of a chromosome 18q deletion.¹⁹³ Two types of regulatory defects in the gene have also been reported, impairing transcription due to hypermethylation of the promoter region¹⁹⁴ or a point mutation affecting transcription factor binding in the promoter.¹⁹⁵ In about 4% of cases a mutation is present on each allele, defining recessive inheritance,^{10, 196} where the majority are missense mutations. Although these few double heterozygotes clarify the phenotypic differences between symptomatic and asymptomatic family members, all other manifesting cases usually coinherit a "low-expression" normal FECH allele trans to a deleterious mutant allele.^{197, 198} The low-expression allele is highly associated with a specific ancestral haplotype involving a single nucleotide polymorphism site in the FECH gene (IVS3-48T/C) that influences the use of a constitutive aberrant acceptor splice site in the gene.¹⁹⁹ The aberrantly spliced RNA fraction is degraded, decreasing the steady-state level of FECH mRNA expressed by the allele by $\geq 20\%$. Hence the term

P.690

"pseudodominant EPP" came into use for patients with a FECH mutation trans to a hypomorphic IVS3-48C allele, to distinguish them from those with autosomal recessive EPP who are hetero- or homoallelic for FECH mutations. The frequency of the hypomorphic IVS3-48C allele differs widely between ethnic groups, ranging from 67.8% in Japanese to <1% in West Africans, and in general correlates with prevalence of clinical EPP among individuals with a mutant FECH allele in the different populations.¹⁷⁶ When a low-expression allele is not found, a dominant-negative effect of FECH mutants may be operative.²⁰⁰ Because the enzyme activity is restricted to its homodimers,²⁰¹ a mutant monomer may generate nonfunctional homodimers and impaired or unstable heterodimers, resulting in residual enzyme activity of <50% of normal.^{202, 203} Thus, the ultimate effect of a specific mutation in the FECH gene depends on how it affects the integrity of the protein and whether the nonmutated allele is expressed at a lower level to reduce FECH activity to below a threshold of around 30% of normal as found in clinically overt EPP.
